
a pleural, pericardial, or peritoneal fluid is of capital importance for the patient and the attending physician or surgeon. Although, in many such instances, a fatal outcome of the disease may be anticipated, some tumors offer a much better prognosis than others. For example, metastatic mammary carcinoma may be controlled, often for a period of many years, by various forms of therapy. In some other tumors, long-term remissions or even cures can be achieved. Malignant lymphomas, some testicular tumors, and some malignant tumors of childhood, such as neuroblastoma or embryonal rhabdomyosarcoma, may respond to energetic therapeutic measures. Therefore, the responsibility of the pathologist is two-fold:

- To identify cancer cells accurately
- To identify tumor type and, if possible, the site of primary origin

These tasks are greatly facilitated by an **accurate clinical history and review of prior histologic material**, if available.

As a general rule, it is better to **exercise diagnostic caution**, keeping in mind the potentially tragic consequences of an erroneous diagnosis of cancer based on flimsy evidence. On the other hand, **failure to recognize cancer cells that show only subtle morphologic abnormalities may delay or deprive the patient of needed treatment.**

The use of impeccable technical preparations is of utmost importance in ensuring diagnostic accuracy. The **collection techniques** are discussed in Chapter 1 and the **laboratory processing techniques** are discussed in detail in Chapter 44. Preparation of **cell blocks** from residual sediment is often of great diagnostic value in the recognition of morphology and origin of the tumor and in the application of special stains or other analytical procedures.

Experimental studies by Siegler and Koprowska (1962) on the **mechanism of ascites formation** in mice indicated that the formation of ascites, containing malignant cells, was **conditioned by damage to the capillaries and lymphatics by colonies of cancer cells.** It is likely that a similar mechanism is operative in humans.

RECOGNITION OF MALIGNANT CELLS

The frequently emphasized difficulty in the recognition and classification of cancer cells in body fluids is caused by two main factors:

- **The body fluids are a natural tissue culture medium, wherein mesothelial and tumor**

cells may proliferate free of the boundaries imposed upon them by the framework of organs and tissues (also see comments in Chap. 25). It is known to all students of in vitro tissue culture that morphologic identification of benign versus malignant cultured cells may be fraught with considerable difficulty. Similarly, the characteristic features of human cancer cells in fluids **may undergo substantial modifications**. For example, **abnormal cell shapes** that often help in the identification of exfoliated or aspirated cancer cells **may no longer be present in fluids, wherein the cancer cells may assume a neutral, spherical appearance**. Nuclear features often seen in cancer, such as **hyperchromasia**, may also be absent or attenuated.

- **Proliferating mesothelial cells may conceal the presence of tumor cells or may mimic cancer cells by forming complex clusters or displaying alarming nuclear features, such as the presence of nucleoli** (see Chap. 25). Rarely, clusters of macrophages (histiocytes) may mimic cancer.

In spite of these words of caution, it is entirely **possible, in the vast majority of effusions, to identify cancer cells accurately, often to identify tumor type, and, sometimes, to suggest the primary tumor of origin**, even in the absence of an accurate clinical history. The diagnostic value and significance of ancillary diagnostic procedures are discussed below (Table 26-1).

The general features leading to the recognition of cancer cells in smears and similar preparations are described at length in Chapter 7. The loss of some of these features in effusions requires close attention to morphologic details that may be of secondary value in other diagnostic media.

Cytoplasmic Features

Cell Size

The size of tumor cells may vary greatly according to tumor type. To determine the size of a suspect cell, a **comparison must be made with identifiable cell types, such as erythrocytes, lymphocytes, or mesothelial cells**. Generally, the cells of malignant tumors in effusions may be classed in three size groups:

- **Large or very large.** The cells are significantly **larger than normal mesothelial cells**. Some mesotheliomas, metastatic **carcinomas of various types, malignant melanomas and sarcomas** belong in this group. When combined with abnormal nuclear features, described below, the identification of such tumors is easy (see Figs. 26-36B, 26-40D, 26-57).
- **Small.** The tumors are made up of cells much smaller than mesothelial cells. Most malignant lymphomas, many of the malignant tumors of childhood (neuroblastoma, Wilms' tumor) and certain carcinomas (small-cell carcinoma of the breast, oat cell carcinoma) belong to this group of tumors. Close attention must be paid to nuclear features and interrelationship of cells for accurate identification (see Figs. 26-28, 26-30, 26-35).
- **Medium-sized.** The diagnostic problem usually occurs with cells of medium size which are approximately of the same size as mesothelial cells. A variety of carcinomas of mammary, lung, gastric, pancreatic, or prostatic origin may have this presentation (see Fig. 26-26). This is perhaps the most difficult group of tumors to identify and the most important source of diagnostic error.

Cell Configuration

Because many cancer cells in fluids assume a “neutral” spherical configuration, unusual cell shapes are very helpful

P.951

in identifying cancer. Thus, the presence of **bizarre or spindly cells** (see Figs. 26-19, 26-20, and 26-57), **columnar cells or cells resembling bronchial lining cells** is usually associated with cancer (see Figs. 26-34, 26-41). **Exceptions** may occur, for example in the sediment in **rheumatoid arthritis** wherein spindly epithelioid cells may be observed (see Chap. 25). Very rarely, **benign fibroblasts**, derived from connective tissue supporting the mesothelium, may also be observed in such fluids.

TABLE 26-1 CELL FEATURES USEFUL IN THE IDENTIFICATION OF CANCER CELLS IN EFFUSIONS

Cell size	Diagnostic value	Benign sources of error
Small	Oat cell carcinoma, some breast cancers, small cell lymphomas, tumors of childhood	Chronic lymphocytic infiltrate (e.g., tuberculosis)
Medium	Many carcinomas	Atypical mesothelial cells
Large	Soft-part sarcomas, some carcinomas	Reactive giant cells (Langhans')
Cell configuration		
Spherical	Dominant in carcinomas	
Bizarre or spindly	Usually diagnostic of a malignant tumor	Rheumatoid arthritis, benign fibroblasts
Other cytoplasmic features		
Keratin formation	Diagnostic of squamous cancer	Squamous epithelial cells from skin (vanishingly rare)
Mucus formation	Diagnostic of metastatic carcinomas of various derivations	No benign counterpart
Cell products		

Melanin pigment	Nearly always diagnostic of malignant melanoma. For exceptions, see text.	Hemosiderin and other hemoglobin-derived pigments
-----------------	---	---

Psammoma bodies	Ovarian, thyroid, mesotheliomas, other rare carcinomas	Dystrophic calcifications of serous cavities (exceptional)
-----------------	--	--

Cell surfaces

Long microvilli (light and electron microscopy)	Mesotheliomas and many carcinomas (<i>not oat cell</i>)	Short orderly surface microvilli on mesothelial cells (on electron microscopy only)
---	---	---

Cell aggregates

Numerous large three-dimensional with lumens on cross section (cell blocks)	Carcinomatous mesothelioma; many carcinomas	Mesothelial cell aggregates, usually small and flat. Exceptionally, macrophages (histiocytes) in nodular histiocytic hyperplasia
---	---	---

Nuclear features

Less hyperchromatic than in other diagnostic media	Many malignant tumors	Rarely enlarged nucleoli in mesothelial cells
--	-----------------------	---

Abnormal N/C ratio		
--------------------	--	--

Large nucleoli		Very rare in mesothelial cells
----------------	--	--------------------------------

Bizarre nuclear shapes (protrusions) and massive apoptosis (karyorrhexis)	Malignant lymphomas	No benign counterpart
---	---------------------	-----------------------

Intranuclear cytoplasmic inclusions	Carcinoma of thyroid, melanoma	
-------------------------------------	--------------------------------	--

(nuclear “holes”)		
Mitoses		
Normal configuration	Suspicious of cancer	Rare normal and exceptionally abnormal mitoses of mesothelial cells and macrophages
Abnormal configuration	Diagnostic of cancer	

Other Cytoplasmic Features

Besides cell size and configuration, there are a few other cytoplasmic features that are sometimes helpful in the identification of cancer cells. **Keratin formation, expressed as thick cytoplasm, staining orange or yellow in Papanicolaou stain**, is practically synonymous with squamous cancers (see Figs. 26-23 and 26-32). **Large, mucus-containing vacuoles**, if accompanied by nuclear abnormalities, occur in cells of **metastatic adenocarcinomas of various derivations**

P.952

(see Fig. 26-41). Such cells must be differentiated from “**signet ring**” **macrophages** that have normal, small nuclei (see Chap. 25). **Intracytoplasmic glandular inclusions (“target cells” or “bull’s eye cells”)** are observed mainly in mammary carcinoma (see Fig. 26-28D) but may sometimes occur in other tumors as well (Kumar et al, 2000).

Rarely, other cytoplasmic features may assist in the identification of tumor types. For example, cancer cells derived from striated muscle, may show the presence of **cytoplasmic cross-striations** (see Fig. 17-6). Such cells are diagnostic of **metastatic rhabdomyosarcomas or tumors with a rhabdomyosarcoma component**, such as metastatic mesodermal mixed tumors.

Cell Products

Products of metabolic activity of cells, such as **mucus** (demonstrated by mucicarmine stain), in cytoplasmic vacuoles, is very rarely, if ever, produced by benign cells in effusions. Accumulation of **intracytoplasmic melanin pigment** (not to be confused with other pigments; see Chap. 25) **is nearly always diagnostic of malignant melanoma** or related tumors (see Fig. 26-56). Calcified, concentrically laminated, round or oval **psammoma bodies**, 20 to 50 µm in size, **are most commonly observed in metastatic tumors of ovarian origin** (see Fig. 26-36), but may also be produced by **thyroid cancer** (see Fig. 26-43), **carcinomatous mesotheliomas** (see Fig. 26-17) and, very rarely, **by bronchogenic adenocarcinoma, pancreatic carcinoma, carcinoma of the renal pelvis, endometrial carcinoma, and mammary carcinoma**. It must be noted that the presence of calcified bodies is of limited diagnostic value in cul-de-sac pelvic washings (see Chap. 16).

Cell Surfaces

Spriggs and Meek (1961) observed the presence of **tufts of hair-like processes on the surfaces of some malignant cells** in pleural and peritoneal effusions, sometimes limited to one segment, but often covering the entire cell (Fig. 26-1). The processes were particularly striking in certain cases of metastatic **ovarian carcinoma**. Ebner and Schneider (1956) also

reported the presence of "ciliated malignant cells" in carcinoma of the ovary.

These early studies have been extended by Domagala and Woyke (1975) and, subsequently, Domagala and Koss (1977). With scanning electron microscopy, it was shown that the **surfaces of most cancer cells in effusions, regardless of tumor type or origin, were covered by innumerable microvilli of variable shape and configuration** (anisovillosis) (Fig. 26-2). **A notable exception were oat carcinoma cells that had a surface without microvilli.** The scanning electron microscopic appearance of the surfaces of cancer cells was markedly different from surface configuration of macrophages and mesothelial cells, described in Chapter 25. Subsequent studies have shown that cells of **carcinomatous mesothelioma** had particularly long, complex microvilli on their surfaces, a feature that is sometimes of diagnostic value (see Fig. 26-1). The significance of microvilli is not understood at the time of this writing (2004).

Figure 26-1 Cluster of cells in a malignant mesothelioma of tunica vaginalis testis in a 21-year-old man. A tuft of long microvilli may be observed on one of the cells. ($\times 2,000$.) (Courtesy of Dr. Arthur Spriggs, Oxford, England)

The microvilli **can be observed in light microscopy** in the form of a **striated halo**, particularly on surfaces of **air-dried cancer cells** (Fig. 26-3). The presence of **visible surface microvilli may be helpful in the recognition of malignant cells**.

Cell Aggregates

Although **benign mesothelial cells may form aggregates** in effusions, as described in Chapter 25, **the aggregates are usually few**, and are usually made up of a **small number of cells**, rarely more than 20 or 25. Further, the aggregates of benign cells are usually arranged in a **monolayer**. Exceptions to this rule have been discussed in Chapter 25. When mesothelial cell aggregates are numerous and composed of a large number of cells, they mimic aggregates formed by malignant tumor cells.

Many **malignant tumors**, principally adenocarcinomas of various primary origin, form **cell aggregates, often composed of a very large number of cells**. Such aggregates are usually three-dimensional, i.e., **made up of several superimposed cell layers** that cannot be brought into a single focus. Approximately round or **spherical aggregates, corresponding to papillary projections, or aggregates forming gland-like structures with a central lumen** (Fig. 26-4A,B), **are particularly helpful in identifying adenocarcinomas**. In cross-sections of these aggregates **in cell blocks, a central lumen is often observed, documenting the glandular or tubular nature of these clusters** (Fig. 26-4C,D). The name of “**spheroids**” or “**hollow spheres**” has been used by some observers to describe such clusters.

Spriggs (1984), in a detailed light and electron microscopic study of cell aggregates in effusions, pointed out that

P.953

these commonly encountered cell clusters are actually **elaborate, organized 3-dimensional structures**. Spriggs divided the structures into three groups: **papillary, tubulopapillary, and acinar** (Fig. 26-5). On cross-section, the cells composing the clusters **surround a lumen, form cell junctions, and often contain central deposits of collagen** as supporting structures. The papillary and tubulopapillary clusters are provided with microvilli on their outer surfaces, whereas the acinar structures contain microvilli on the surface facing the lumen. Thus, **the cell aggregates**, far from being haphazard accumulations of epithelial cells, are, in fact, **highly organized structures formed by benign or malignant cells, growing freely in effusions**.

Figure 26-2 Scanning and transmission electron microscopy (TEM) of cancer cells in effusions. *A.* Cluster of cancer cells from a metastatic ovarian carcinoma. Note innumerable microvilli on the surfaces of cancer cells. *B.* Breast cancer cell. Note shaggy appearance due to numerous slender microvilli. *C.* Lung cancer cell (adenocarcinoma). Short stubby microvilli are adjacent to long slender microvilli. *D.* Cell of ovarian carcinoma in TEM. Note innumerable microvilli of uneven size and configuration on the cell surface. (*A*: $\times 2,300$; *B*: $\times 4,600$; *C*: $\times 6,000$; *D*: $\times 18,600$.) (Courtesy of Dr. W. Domagala, formerly of Montefiore Hospital, New York, NY.)

Nuclear Features

Nuclear Configuration, Size, and Shape

As has been mentioned above, nuclear hyperchromasia and coarse granularity of chromatin, important landmarks of cancer cells in other media, may not be evident in effusions. The nuclei may be **homogeneous and opaque and sometimes clear and transparent**.

Figure 26-3 Microvilli on the surface of cancer cells. *A.* Alcohol fixation. *B.* Air-dried smear (oil immersion). The microvilli are better seen in the air-dried material.

Still, most malignant cells in fluids have **enlarged nuclei**, corresponding to increased DNA content. In most but not all carcinomas, the **nucleocytoplasmic ratio is modified in favor of the nucleus**, particularly when compared with mesothelial cells (see Fig. 26-36). However, in some **mucus-producing** and **keratinizing squamous cancer cells**, the cytoplasm is abundant and the **nucleocytoplasmic ratio may not be conspicuously abnormal**.

Figure 26-4 Spherical clusters characteristic of malignant mesothelioma and adenocarcinoma. *A.* A large number of spherical clusters in pleural fluid in a 43-year-old man with malignant mesothelioma. *B.* High-power view of one of the clusters from *A* showing a spherical configuration of the cells forming the cluster. *C.* Cross-section of one of the spherical clusters showing formation of an empty (gland-like) space within the cluster. *D.* A cell block from another case showing the glandular arrangement of the cells of adenocarcinoma immunostained for low density keratin.

The **nuclear shapes** of cancer cells in fluids are **rarely abnormal**. Most such cells display **spherical or oval nuclei**

with smooth borders. Occasionally, on closer scrutiny, an **irregular nuclear outline** may be observed and is of **diagnostic assistance**, particularly in **malignant lymphomas**, in the form of **indentations or protrusions** of the nuclear membrane. Another nuclear feature observed in malignant effusions, particularly in **malignant lymphomas**, is **massive nuclear breakdown (apoptosis or karyorrhexis)** that is virtually never seen in benign fluids (see Figs. 26-46, 26-47).

Nucleoli

The presence of nucleoli is of capital diagnostic importance in the recognition of cancer cells in effusions. Except in keratinizing squamous carcinomas, large, irregularly shaped, single or multiple nucleoli are frequently observed in cancer cells (see Fig. 26-55). As described in Chapter 25, on rare occasions, enlarged nucleoli may occur in mesothelial cells, which then become an important source of error.

Figure 26-6 Abnormal mitoses in cancer cells in fluids. *A.* Quadripolar mitosis in pericardial fluid with metastatic carcinoma. *B.* An abnormal metaphase in pleural fluid in the presence of a sarcoma. *C.* Abnormal mitosis in pleural fluid in metastatic carcinoma. *D.* Typical prophase in the nucleus of a cancer cell in pleural fluid (*A, B, D:* high magnification.)

Mitoses

Mitoses are very rare in benign fluids and, therefore, their presence should be considered as presumptive evidence of cancer. Abnormal mitotic figures, such as an increase in the number of chromosomes, multipolar mitoses or chromosomal lag (see Chap. 7), are one of the most reliable identifiers of cancer cells in effusions (Fig. 26-6A-C). Occasionally, the nuclear area is filled with

P.956

chromatin granules, suggestive of a mitotic prophase (Fig. 26-6D). These findings are uncommon in benign cells and should also be considered as a possible presumptive evidence of a malignant tumor.

However, as discussed in Chapter 25, **we observed morphologically atypical mitoses in mesothelial cells in pleural fluid in the absence of cancer** in two patients, out of many thousands examined. Papanicolaou, in his *Atlas* (1954), also mentioned two similar cases. It may be stated safely that **such occurrences are extraordinarily rare and should not detract from the diagnostic value of abnormal mitotic figures, which very strongly suggest a malignant process.** It is conceivable that chromosomal abnormalities observed in mesothelial cells in ascites in cirrhosis of the liver, discussed in Chapter 25, may account for the rare mitotic abnormalities observed in benign effusions.

Multiple Sex Chromatin (Barr) Bodies

As mentioned in Chapters 7 and 11, in **female patients, two or more sex chromatin bodies in the same nucleus are virtually diagnostic of cancer because they document the presence of an abnormal chromosomal complement.** This observation is particularly helpful in the diagnosis of some cases of **metastatic mammary carcinoma**, wherein the size of the cancer cells may be comparable to that of mesothelial cells or macrophages, and the

morphologic abnormalities are not pronounced (see Fig. 26-27B). **Mesothelial cells and macrophages (histiocytes) have a single sex chromatin body**, except in the extraordinary rare superfemales (karyotype 47, XXX). The multiplicity of sex chromatin bodies in cancer cells is sometimes difficult to ascertain because large chromocenters, located near the nuclear membrane, may be misinterpreted as Barr bodies. Thus, the shape and location of the sex chromatin body must be carefully assessed (for further discussion and description of sex chromatin bodies, see Chaps. 4, 7, and 21).

Nuclear Cytoplasmic Inclusions (Orphan Annie Nuclei)

Sharply demarcated clear areas within the nucleus, corresponding to cytoplasmic invaginations, have been observed in a variety of cancer cells, but mainly in cells of **metastatic melanomas, thyroid cancers and pulmonary adenocarcinomas** (see Fig. 26-55). **We have never observed this feature in benign cells in effusions.**

ANCILLARY TECHNIQUES IN THE RECOGNITION OF CANCER CELLS IN EFFUSIONS

Cytogenetics

The finding of **cells with abnormal chromosomal numbers and configuration has been shown to be diagnostic of cancer cells in effusions** (Goodlin, 1961; Ishihara and Sandberg, 1963; Jackson, 1967).

Benedict et al (1971) pointed out that a **long acrocentric chromosome** was often associated with **metastatic malignant tumors**, regardless of primary origin and histologic type. Miles and Wolinska (1973) **compared the sensitivity of cytogenetic studies with light microscopic diagnoses in 58 cancer patients**. In 38 patients, routine cytology disclosed cancer, whereas cytogenetic studies were positive in only 24 of these patients. However, in two patients, chromosome analysis disclosed an aneuploid chromosomal component, whereas routine cytology was negative. Cytogenetic studies in this group of patients may have been handicapped by prior treatment. In general, **tissue culture technique** is used to obtain a sufficient number of metaphases for cytogenetic analysis. Otherwise, a very large population of dividing cancer cells is required for a successful direct chromosomal analysis.

The apparent **exceptions to this rule** are the observations by To et al (1981) and by Watts et al (1983) who observed abnormal chromosomal components in several ascitic fluids associated with liver cirrhosis and in one pleural effusion associated with pneumonia (see Chap. 25).

Apparently, other disorders, such as rheumatoid arthritis or pulmonary embolus, may occasionally be associated with chromosomal abnormalities (summary in Watts et al, 1983). These studies did not include chromosomal banding. It would be of great interest to confirm these observations by contemporary cytogenetic techniques.

With the introduction of **molecular probes** to various chromosomes, it became possible to determine chromosomal abnormalities by the technique of **fluorescent in situ hybridization (FISH) in interphase nuclei**. The principles of this technique are discussed in Chapter 4. The application of this technique to malignant mesotheliomas in effusions is discussed below (Granados et al, 1994). Florentine et al (1997) used probes to **chromosomes 3, 8, 10, and 12 to determine numerical chromosomal aberrations**, and compared the results of chromosomal analysis with conventional cytology on ThinPrep (Cytoc Corporation, Boxborough, MA) slides of effusions with mixed results. Cajulis et al (1997) specifically identified **difficult-to-**

classify “atypical” cells in previously stained smears in a variety of samples (including four effusions). They used the FISH technique to determine numerical aberrations **of chromosome 8**. Cajulis observed chromosomal aberrations in most “atypical” cells but not in benign cells and considered the **FISH technique with chromosome 8 to have a specificity of 100% and sensitivity of 83%**. The reader is cautioned that the FISH technique requires a dedicated laboratory and that the molecular probes to individual chromosomes or their centromeres are expensive. Nonetheless, the results cited are most encouraging and suggest that the technique may prove to be very useful in determining the presence or absence of cancer in difficult cases. The results of FISH technique in cells in the **urinary sediment** are discussed in Chapter 23.

A novel approach to the identification of cancer cells is the documentation of **telomerase activity**. **Telomeres** are the structures capping the ends of normal chromosomes. With each cell division, the **telomeres become shorter**, resulting in cell senescence. It is assumed that the enzyme **telomerase is capable of synthesis of telomeres, thus conferring**

P.957

immortality on cancer cells. Telomerase activity can be demonstrated by molecular biologic techniques or by immunochemistry using an **in situ fluorescent assay** and a **telomere repeat amplification protocol (TRAP)** (Ohyashiki et al, 1997). The test results in **nuclear fluorescence in cancer cells** whereas, in benign cells, the fluorescence is limited to the cytoplasm. Dejmek et al (2001) adopted this technique to cells in 16 effusions **and claimed that the test was specific for cancer cells**. Similar data were previously provided for cancer cells in the respiratory tract (Dejmek et al, 2000) and in urinary sediment (Ohyashiki et al, 1998). However, Braunschweig et al (2001) denied any diagnostic value to the TRAP reaction because of frequent false-positive and false-negative results.

DNA Measurements in Effusions as Tumor Markers

Freni et al (1971) and Krivinkova et al (1976) were apparently the first groups of investigators to recognize the **diagnostic value of DNA measurements by cytophotometry in the identification of malignant cells in effusions**. The presence of cells with abnormal DNA content was well correlated with the presence of cancer.

With the introduction of **flow cytometry**, the DNA measurements became more rapid and several groups of investigators reported **abnormal DNA histograms in fluids containing malignant cells** (Evans et al, 1983; Unger et al, 1983; Katz et al, 1985; Croonen et al, 1988). In a study from this laboratory, Schneller et al (1987) pointed out that static **cytophotometry may disclose abnormal DNA values in cancer cells that are not revealed by flow cytometry**. Further, some malignant tumors are diploid and have a perfectly normal DNA ploidy that cannot be detected by any measurements. Agarwal et al (1991) observed that some benign tumors have an aneuploid DNA distribution. Thus, **an abnormal DNA histogram usually (but not always) indicates the presence of cancer but a normal diploid histogram does not necessarily rule out cancer**. For further discussion of cytophotometry and flow cytometry, see Chapters 46 and 47.

Cytochemistry and Immunocytochemistry

Cells in effusions are the favored target of cytochemical and immunocytochemical investigations because of abundant cell populations and the ease with which multiple samples can be obtained in the form of smears, cytocentrifuge preparations (cytospins), cell blocks (cell buttons) or the newer methods of processing of liquid samples (ThinPrep). **There are no specific cytochemical or immunocytochemical reagents that could distinguish benign**

from malignant cells. The best effort along these lines was the use of an **antibody to the mutated p53 molecule** that is commonly expressed in human malignant tumors and practically never in normal tissues (see Chaps. 3 and 7). Mullick et al (1996) applied this antibody to 103 effusions and reported positive staining in 55% of malignant tumors and none in benign controls. Otherwise, these techniques are sometimes helpful in **distinguishing from each other tumors of diverse origins and type.**

The most useful cytochemical stains are **mucicarmine** that are frequently helpful in differentiating cancer cells from mesothelial cells, stains for the **identification of pigments, such as melanin and some silver stains**, all discussed in Chapter 44. The number of monoclonal antibodies tested on effusions is very large and the principal observations are discussed in Chapter 45. Hence, only a brief summary of the most useful antibodies is shown in Table 26-2. A **multiple-well technique**, which permits synchronous testing of several aliquots of cells with several monoclonal antibodies, was described by Guzman et al (1988).

Regardless of results, the **immunocytochemical observations must be considered a secondary mode of cancer cell identification that may sometimes enhance, but never replace, morphologic observations.**

Immunologic Response

Another approach of current interest in the study of effusions is the **relationship of various cell populations engaged in immune responses to cancer cells in effusions.**

Scanning electron microscopic studies by Domagala and Koss (1977) strongly suggested that **cell contacts between lymphocytes and macrophages and between macrophages and cancer cells may occur in effusions** (Fig. 26-7A). The latter relationship has since been confirmed in light microscopy. Cancer cells in contact with variable numbers of macrophages have been repeatedly observed (Fig. 26-7B). **Phagocytosis of cancer cells**, either by macrophages or by other cancer cells may also be observed (Fig. 26-7C).

Domagala et al (1978, 1981) also studied the **distribution of B and T lymphocytes** in the peripheral blood and in effusions of patients with metastatic carcinoma of various primary origins. In most cases, there was a **statistically significant increase of T lymphocytes in fluids with metastatic cancer.** Similar observations have been made by Djeu et al (1976). Green and Griffin (1996) observed an **increase in the subset of lymphocytes known as natural killer cells** (identified by antibodies to CD16/CD56) in 14 of 15 patients with **metastatic carcinomas in pleural effusions.** However, **mesotheliomas, lymphomas and leukemias did not show this abnormality.** These observations were confirmed by Laurini et al (2000) who used flow cytometry with the same monoclonal antibodies in their studies. These reports suggest that immune mechanisms are operative in some effusions with metastatic cancer and that their further exploration may be of diagnostic and perhaps prognostic significance.

IDENTIFICATION OF TUMOR TYPES

The diagnosis of tumor types, such as **adenocarcinomas, squamous carcinomas, tumors with endocrine function, malignant lymphomas, or sarcomas in effusions, is of**

significant clinical value. This information may help in the determination of the organ of origin of the tumor and provide guidance to optimal treatment. The **best chances of identification of tumor type** occur when **cancer cells form multicellular structures akin to those**

P.958

observed in tissues or if fragments of tumor can be recognized in cell blocks. Other identification options are based on **cell relationships and identification of cell products.** The **three most common types of tumors** encountered in effusions are: **adenocarcinomas, poorly differentiated carcinomas of various origins, and small cell tumors.** Less often, **keratinizing squamous carcinoma** may also be recognized. Many of the features of malignant cells described above may serve to identify tumor types.

TABLE 26-2 MONOCLONAL ANTIBODIES USED ON EFFUSIONS

Antibody	Purpose
Keratin: AE1/AE3	To distinguish carcinoma from other types of tumors.
Common lymphocyte antigen: LCA	To mark lymphoid cells.
Lymphocyte markers: CD3	In combination with CD 20, to distinguish lymphoma from reactive lymph node.
Lymphocyte markers: CD20	In combination with CD 3, to distinguish lymphoma from reactive lymph node.
Endocrine markers: Synaphophysin	For neuroendocrine tumors.
Endocrine markers: Chromogranin	For neuroendocrine tumors.
Calretinin	To distinguish mesothelial cells from other epithelial cells.
HMB 45	To favor melanoma.
Intermediate filament: Vimentin	For mesenchymal lesion, and in combination with AE1/AE3 for renal cell carcinoma.

Figure 26-7 Macrophages and phagocytosis in cancer. *A.* Scanning electron micrograph showing an extension of the cytoplasm of a macrophage onto the surface of a cancer cell identified by microvilli. *B.* High magnification view of a large cancer cell surrounded by macrophages, corresponding to the scanning electron microscopy image shown in *A.* *C.* Phagocytosis of cancer cells, presumably by other cancer cells. This cell arrangement is not uncommon in cancer but may also occur in cirrhosis of the liver.

Adenocarcinomas

Adenocarcinomas of various origins are by far the most common type of tumors encountered in effusions. The common features of adenocarcinomas in fluids are:

P.959

- **The tumor cells form gland-like or tubular structures with a central lumen** (see Fig. 26-4).
- Tumor cells forming **multilayered, spherical or oval cell clusters, suggestive of papillary growth, also known as “spheroids” or “hollow spheres”** (see Fig. 26-4A,B). In paraffin-embedded cell blocks, cross-sections of such clusters usually reveal **glandular features of adenocarcinoma** (see Fig. 26-4C,D).
- **Single cells of adenocarcinoma may be recognized if they are of columnar configuration because such cell types practically never occur in other tumor types.**
- **Signet ring cancer cells, with an abnormal nucleus displaced to the periphery by a large mucus vacuole** (see Fig. 26-41). **It is important to emphasize that the mere presence of cytoplasmic vacuoles is not diagnostic of adenocarcinoma, unless the nuclei of these cells display malignant features and the presence of mucus can be documented. Cytoplasmic vacuoles may occur in tumor cells of various types and in benign cells such as macrophages** (see Chap. 25 and Fig. 25-41).

Other cell features may identify adenocarcinomas of specific origins, described below. However, there will always remain a group of metastatic poorly differentiated adenocarcinomas in which a specific identification of tumor type will prove difficult (see below).

Poorly Differentiated Carcinomas, Large-Cell Type

Effusions containing cells of poorly differentiated carcinomas are **easily identified as malignant** but the **identification of tumor type in effusions is often difficult**, particularly the separation of a metastatic nonkeratinizing squamous (epidermoid) carcinoma from poorly differentiated adenocarcinomas of various origins.

- Depending on the primary tumor, the **tumor cells vary in size. Within each fluid, however, the variability of the cell sizes is usually limited.**
- The tumor cells are usually **dispersed or form loosely structured, irregular clusters.**
- Cross-sections of such clusters in cell blocks usually reveals solid tumors. The tumor cells have a **fairly abundant cytoplasm** that is usually transparent and basophilic. Still, cytoplasmic vacuoles may occur in some cancers, particularly of renal origin.
- **The nuclei** are usually large, sometimes of irregular configuration, and are **often hyperchromatic and they often contain large, irregular, sometimes multiple nucleoli** (see Fig. 26-32D).

Small-Cell Tumors

Tumors composed of small cells may be of epithelial origin such as oat cell carcinoma and related tumors and small cell tumors of the breast or of other derivation, such as malignant small cell tumors of childhood, or malignant lymphomas. The principal difficulty in the recognition of this group of malignant tumors in effusions is the **small size of cancer cells** that **may be overlooked or mistaken for inflammatory cells**. Once the hurdle of recognition is overcome, the cytologic presentation of these tumors is quite characteristic and is discussed and illustrated below.

Keratinizing Squamous Carcinoma

Well-differentiated, keratin-producing squamous cancers can be readily identified but are **rarely observed in effusions**. The reasons for this are not clear. Spriggs (1954), in discussing effusions in lung cancer, also pointed out the rarity of identifiable squamous carcinoma. The principal features of these cancers in fluids are:

- The presence of **keratinizing squamous cells, regardless of nuclear structure**. Quite often, the squamous cancer cells in effusions **resemble normal squamous cells** (see Fig. 26-33). Contamination with squamous cells of the epidermis removed during the aspiration procedure is very rare and then it results in only a few such cells or actual fragments of skin epidermis. The one exception to this rule, cited in Chapter 25, was the exceptional case of a ruptured benign dermoid cyst of the mediastinum.
- The presence of **anucleated squames of odd shapes and sizes**. More commonly, the **nuclei appear necrotic, shadowy, and pale** (see Fig. 26-33A,B).
- **Squamous pearl formation, when present, is absolutely diagnostic of this type of cancer** (see Fig. 26-23).

Mesotheliomas, neuroendocrine carcinomas, malignant lymphomas and other specific tumor types are discussed below in reference to organs of origin.

PRIMARY TUMORS OF BODY CAVITIES

Mesotheliomas

Classification

Klemperer and Rabin (1931) were apparently the first to propose that **tumors involving mesothelial surfaces may be either of mesothelial cell or connective tissue origin**. This is consistent with the current consensus on the origin of these tumors (Battifora and McCaughey, 1994).

The following simple classification of primary tumors of mesothelial lining is proposed, based on prior personal study of material from the Memorial Hospital for Cancer and Allied Diseases, and also adopted by Ratzer et al (1967). This classification is similar to that proposed by Battifora and McCaughey (1994).

Tumors of mesothelial lining cells

Benign

Benign, reactive proliferations of mesothelial cells, mimicking mesothelioma

Papillary mesothelioma

Abdominal multicystic mesothelioma

Malignant

Carcinomatous (epithelial) mesothelioma and its variants

P.960

Tumors of supporting connective tissue

Benign

Fibrous pleural plaques.

Fibromas (cellular or hyalinized)—often referred to as fibrous mesotheliomas

Malignant

Fibrosarcomatous mesothelioma

Mixed tumor types

Synovioma-like mesothelioma

Anatomic Distribution

Benign proliferations of the mesothelium may be observed on the surface of the **visceral pleura** as a reaction to pulmonary tumors, infarcts or, occasionally, other events, discussed in Chapter 25. Similar events may be sometimes observed in hernia sacks, tunica vaginalis testis and, rarely, other sites (see Chap. 33).

Benign tumors of mesothelial cells are rare. The tumor most frequently observed is **papillary mesothelioma** that has been observed in the pleura, peritoneum, pericardium, and even the tunica vaginalis testis (Becker, 1976; Daya and McCaughey, 1990; Hoekman et al, 1996; Xiao et al, 2000; Butnor et al, 2001). The tumors are symptomatic, may be accompanied by effusions, and are observed mainly in younger patients without asbestos exposure. Favorable

outcome of surgical resection of the tumor was reported by Becker (1976), Sane and Roggli (1995) and Hoekman et al (1996). Butner et al (2001) reported less satisfactory outcome in some patients. Hejmadi et al (2003) reported a malignant transformation of one such tumor. Another unusual, apparently benign, tumor of the abdominal cavity is **multicystic mesothelioma** (Baddoura and Varma, 1990; Kampschoer et al, 1992).

Carcinomatous (Epithelial) Mesotheliomas

Epidemiology

Exposure to asbestos fibers, as it occurred in shipyard workers during World War II, has been shown to be an important etiologic factor in the **genesis of carcinomatous mesotheliomas and of lung cancer** (reviews in Selikoff et al, 1965; O'Donnell et al, 1966; Wagner, 1991; Price, 1997; see also Chaps. 19 and 20). Not all types of asbestos fibers have the same pathogenetic significance. Long, thin **crocidolite and amosite fibers**, mined in South Africa, have a **high level of association with pleural mesotheliomas**. The association with **chrysotile fibers** mined in North America is low (reviews in McDonald and McDonald, 1980; Craighead and Mossman, 1982; Pisani et al, 1988; Mossman et al, 1990). Because the asbestos fibers are ubiquitous (see Chap. 19), their mere presence in lung tissue or the mesothelium does not necessarily lead to tumor formation. **Benign pleural fibrous plaques** containing asbestos fibers are found with greater frequency than mesotheliomas (Fig. 26-8) (Rous and Studeny, 1970; Roggli and Pratt, 1992).

Figure 26-8 Asbestos bodies in the pleura. A. Elongated asbestos bodies embedded in pleural connective tissue. B. Ferruginous body digested from the pleura.

Pleural carcinomatous mesotheliomas are, in many **but not all cases, an occupational disease** in people with a high level of exposure to carcinogenic asbestos. Thus, besides shipyard workers, miners of high-risk asbestos, and insulation workers, may develop the disease. Still, in a substantial proportion of patients, probably close to 25%, **no occupational hazard could be identified** (McDonald and McDonald, 1980; Petersson et al, 1984; Brochard et al, 1993; Pairon et al, 1994). The relationship of **asbestos exposure to peritoneal carcinomatous mesotheliomas, papillary mesotheliomas, and fibrosarcomatous mesotheliomas is much less secure.**

The relationship of **carcinomatous mesothelioma** to asbestos exposure is illustrated by **epidemiologic data**. The peak of the disease in the United States was observed in the years 1960-1990 affecting mainly World War II shipyard workers who were exposed to huge amounts

of asbestos fibers. In recent years, there has been a substantial drop in the frequency of this disease as the shipyard workers died out and stringent controls on industrial asbestos exposure have been instituted. Thus, Price (1997) projected that, in the year 2000, there will be about 2,300 cases in men and

P.961

500 in women. Price also estimated that, over the next 50 years, the rate in men will diminish to equal that in women, at about 500 cases a year.

At the time of this writing (2004), there are no reliable epidemiologic data on other types of mesothelial tumors.

Simian virus 40 was proposed as another possible cause of malignant mesothelioma (Carbone et al, 1994, 1997). The virus was a contaminant of various vaccines. The large T antigen of the virus was alleged to be the oncogenic factor in the formation of these tumors (De Luca et al, 1997; Mulatero et al, 1999). Simsir et al (2001) were unable to document the presence of the viral antigen in the nuclei of cancer cells, either in mesotheliomas or other tumors. It is of interest that spontaneous peritoneal mesotheliomas of viral etiology occur in the golden hamster (Mehnert et al, 1974).

Most people develop mesotheliomas in the sixth decade of life or later, but a case was described in an **infant** (Chu et al, 1989) and several in **childhood** (Grund and Miller, 1972; Kovalivker and Motovic, 1985). There is also a known **familial occurrence** of this tumor (review in Hammar et al, 1989). **Papillary mesothelioma** has been observed mainly in premenopausal women (Hoekman et al, 1996).

With a few exceptions of anatomically limited malignant carcinomatous mesotheliomas successfully treated by surgery (Antman et al, 1985), the **prognosis of the disease is rather grim**, resulting in death within a year or two. An accurate cytologic diagnosis of a malignant mesothelioma early in the disease may, perhaps, contribute to salvage of these patients. It is of interest that, in some personal cases, the **cytologic diagnosis of a carcinomatous mesothelioma was established in pleural fluid several years before the tumor became apparent and confirmed by biopsy. The slow evolution of some malignant mesotheliomas has not been emphasized in the literature.**

The most common **primary site of malignant carcinomatous mesotheliomas is the pleura, followed by the peritoneum and, occasionally, the pericardium. Simultaneous or sequential involvement of two or all three body cavities** by these tumors may occur (Sytman and MacAlpin, 1971; Ascoli et al, 1996). Primary carcinomatous mesotheliomas may also occur in **hernia sacs, in the tunica vaginalis testis, and on the surface of the ovary** (Parmley and Woodruff, 1974; Japko et al, 1982; Jones et al, 1995; Clement et al, 1996; Attanoos and Gibbs, 2000).

Effusions as the First Manifestation of Mesotheliomas

Pleural or pericardial effusions and ascites are the usual first manifestation of carcinomatous mesotheliomas. In my experience, **effusions are exceptional as the first manifestation of benign mesothelial proliferations, pleural plaques or benign or malignant tumors of connective tissue origin.** Pleural effusion was not observed in any of the patients with benign pleural tumors seen at the Memorial Hospital (Ratzer et al, 1967). Only 1 of the 18 patients with benign mesothelioma of the pleura reported by Foster and Ackerman (1960) had pleural effusion. Most of these tumors were observed on chest radiographs. In **sarcomatous mesotheliomas**, effusions may occur **late** in the course of the disease. Only

one of the five patients with sarcomatous mesotheliomas had an effusion in the small series described by Klima et al (1976). Thus, an **effusion as the first manifestation of disease, particularly in an elderly patient with a past history of occupational hazards, should raise the possibility of a carcinomatous mesothelioma.**

Histology

Carcinomatous mesotheliomas are composed of **large malignant cells with abundant eosinophilic cytoplasm and large but pale vesicular nuclei, forming glandular or tubular structures**, often separated from each other by connective tissue septa. Papillary excrescences are commonly observed in tumor glands (Fig. 26-9A,B). Some mesotheliomas produce a great deal of hyaline connective tissue and have been singled out as **desmoplastic mesotheliomas** (Fig. 26-9C) (Battifora and McCaughey, 1994). Some mesotheliomas combine glandular and connective tissue features and are considered "mixed type" (Fig. 26-9D; and below). In my experience, the recognition of carcinomatous mesothelioma and its separation from primary bronchogenic or metastatic adenocarcinomas is easy in adequate tissue samples because of diagnostic clues that are often available on the **mesothelial surface of the tumors:**

- **Mesothelioma in situ** is an abnormality often observed in mesothelium of origin or adjacent to the main tumor, consisting of a **layer of malignant mesothelial cells lining the surface**. The cancerous cells, often **arranged in a palisade, are larger than normal mesothelial cells, are frequently elongated, club or tennis racquet-shaped**, and are attached by the narrow end to the surface of the organ; their nuclei are large and contain distinct, often multiple nucleoli (Fig. 26-10A). In **abdominal tumors, mesothelioma in situ may be observed on the surface of the spleen capsule**. Henderson et al (1998) suggested that the diagnosis of mesothelioma in situ should be limited to patients with documented invasive tumors. but we have sometimes offered this diagnosis in the absence of invasive tumor under appropriate clinical circumstances. Mesothelioma in situ is often accompanied by marked proliferation of large mesothelial cells (Fig. 26-10B).
- **The formation of delicate, spherical papillary structures on tumor surface** (Fig. 26-10C). Sometimes, the mesothelial cells form papillary projections in which a **central thin, branching core of connective tissue is lined with a single or double layer of oval, round, or slightly elongated eosinophilic cells of variable size**. The similarity of these structures to a "Christmas tree" is sometimes striking. Transitions between the in situ changes and the papillary structures are frequently observed (Fig. 26-10D).

Because these features are not always evident in small biopsies, **carcinomatous mesotheliomas may be very difficult to differentiate from a benign mesothelial proliferation**

P.962

on one hand and, on the other hand, from poorly differentiated bronchogenic adenocarcinoma or large cell undifferentiated carcinoma and occasionally metastatic tumors. Of special interest in the differential diagnosis of carcinomatous mesothelioma is **mesothelial proliferation that may be observed in lung cancer** (Yokoi and Mark, 1991) and a **peripheral form of pulmonary adenocarcinoma with pleural fibrosis** described by Harwood et al (1976) as a pseudomesotheliomatous carcinoma. In a recent review of this rare tumor, unilateral pleural effusions were observed in most of the 30 patients (M. Koss et al, 1992).

Figure 26-9 Various aspects of carcinomatous mesothelioma. *A,B.* Typical tumor composed of sheets of large cells with large connective tissue septa. *C.* Tumor with a marked desmoplastic reaction. *D.* Tumor showing components of adenocarcinoma and spindle cell neoplasm, hence mesothelioma of mixed type.

The US-Canadian Mesothelioma Reference Panel (Churg et al, 2000) listed a number of criteria separating benign from the malignant mesothelial proliferation but did not sufficiently stress **the importance of clinical observations. As mentioned above, effusions are rarely observed as a primary event in benign lesions but are a dominant feature in carcinomatous mesotheliomas** (M. Koss, 2001). The cytologic presentation of effusions is also of diagnostic help in many cases. Ancillary procedures helpful in the differential diagnosis are discussed below in reference to cytologic presentation of these lesions.

Carcinomatous Mesotheliomas With Deciduoid Features

There are several case reports of mesotheliomas with **deciduoid morphology** and generally poor prognosis. These uncommon tumors are, in part, composed of large cells with **eosinophilic cytoplasm and central large nuclei**, resembling morphologically the decidua. These tumors were initially observed in the **peritoneum of young female patients** (Talerman et al, 1985; Nascimento et al, 1994). Subsequent reports noted that such tumors may also occur in the **pleura and even in the pericardium** of older patients of both sexes

P.963

(Shanks et al, 2000; Reis-Filho et al, 2002). Serio et al (2002) reported two cases with long-term survival.

Figure 26-10 Surface of malignant mesothelioma. *A.* Typical in situ mesothelioma on the surface of the pericardium. Note the tennis racquet-shaped cells arranged in a palisade. *B.* Papillary proliferation on the surface of well differentiated carcinomatous mesothelioma. *C,D.* Papillary proliferations on the surface of other malignant mesotheliomas.

Papillary Mesotheliomas

These are uncommon and usually benign tumors composed of slender fronds of connective tissue lined by one or two layers of morphologically normal mesothelial cells (Daya and McCaughey, 1990; Hoekman et al, 1996; Butnor et al, 2001). The tumors are usually symptomatic and occur mainly in the peritoneum but may also be seen in the pleura and even the pericardium (Becker et al, 1976). A malignant transformation of one such tumor was reported by Hejmadi et al (2003).

Multicystic Peritoneal Mesothelioma

Several cases of this very rare disorder have been reported. The cysts are lined by morphologically normal mesothelial cells (summary in Weiss and Tavassoli, 1988; Alvarez-Fernandez et al, 1989; Kampschoer et al, 1992). The disease must be differentiated from other cystic tumors of the abdominal cavity, notably of ovarian origin. The neoplasm appears to be of low grade, capable of recurrence, but consistent with long-term survival.

Cytology

An accurate assessment of effusions, which are often the first evidence of disease, is of paramount importance in the diagnosis of carcinomatous mesothelioma. The tumors often, but not always, shed **abundant malignant cells**. **Although these cells occur singly, the dominant feature is often the presence of numerous spherical cell clusters** (see Figs. 26-4A-C, 26-11). The clusters are three-dimensional, often show scalloped edges, and thus resemble mulberries. The term “**morulae**” is in common use in describing such clusters. The morulae are often **superimposed on each other, forming complex clusters similar to overlapping circles** (see Fig. 26-17A). The “**morulae**” are usually **larger and more**

complex than any clusters of benign mesothelial cells observed in this laboratory. Occasionally, the clusters contain a **central core of connective tissue** (Fig. 26-11C). In the presence of **numerous 3-dimensional, mulberry-shaped papillary clusters of cells** in an effusion of a **patient without a known primary cancer**, the diagnosis of a **carcinomatous mesothelioma** should be considered.

Single cancer cells are usually larger than normal mesothelial cells which they may closely resemble because of abundant, occasionally faintly vacuolated cytoplasm, often with a distinct, **clear periphery and denser**

P.964

perinuclear area (Figs. 26-12C, 26-13B,C). Sometimes cytoplasmic vacuoles may occur (Fig. 26-14A). The **nuclei, which are usually single but may be double or, rarely, multiple, are enlarged and may show irregular contour. The nuclei are sometimes hyperchromatic, but more often open and vesicular and may contain a variable number of large, sometimes irregularly shaped nucleoli.** The nucleocytoplasmic ratio is not necessarily shifted to the nucleus because of the large cytoplasmic area. Another feature of carcinomatous mesothelioma that is sometimes helpful is the **presence of long microvilli on the surface of the tumor cells.** The microvilli may be seen under the high power of a light microscope and are better visualized in air-dried preparations, where the cells are spread on the surface of the slide before fixation (see Figs. 26-3, 26-13C). Electron microscopy usually reveals long, complex microvilli on the surfaces of cancer cells (see Fig. 26-18).

Figure 26-11 Carcinomatous mesothelioma. *A.* Numerous papillary clusters in the pleural fluid of a 20-year-old man. *B.* Papillary clusters of cells, stained with May-Grünwald-Giemsa. *C.* Cross-section of one of the papillary clusters in a cell block, with a core of connective tissue and periphery composed of tennis racquet-shaped malignant cells. *D.* Papillary clusters of an epithelial mesothelioma giving a positive (brown) immunoperoxidase calretinin stain.

Calcified bodies, similar to **psammoma bodies**, were seen on several occasions (Fig. 26-14B). **Mitotic figures**, some abnormal, are often observed and, with very rare exceptions,

confirm the diagnosis of a malignant tumor.

In some cases, the tumor cells are only slightly enlarged when compared with normal mesothelial cells. The difficulty of differentiating such cells from benign mesothelial cells has been emphasized by other observers, notably Klempman (1962), Naylor (1963), and Bengé and Grontoft (1964). Recent contributions on this subject do not provide any new information on the morphology of these cells (Granados et al, 1994; Renshaw et al, 1997). However, in my experience, in virtually every case of carcinomatous mesothelioma, one sees **at least a few cells with nuclear and cytoplasmic abnormalities of a sufficient degree to make the diagnosis of a malignant tumor possible.**

Differences Between Carcinomatous Mesotheliomas of the Pleura and the Peritoneum

In 1982, Boon et al compared the cytologic presentation of primary pleural and peritoneal mesotheliomas. She noted, **in air-dried, Giemsa-stained smears, that the cytoplasmic area of the pleural mesothelioma cells was smaller and contained few cytoplasmic vacuoles.** Many of the **cells of the peritoneal mesotheliomas were larger and characterized by numerous perinuclear vacuoles.** Other features, such as cluster (morulae) formation were similar for both tumor types. Further analysis of the cytoplasmic vacuoles was provided by Boon et al in 1984. The vacuoles in malignant mesothelioma cells stained for

P.965

fat, but not for mucin, contrary to vacuoles in metastatic cancer. It was also acknowledged that the vacuolated appearance of mesothelioma cells was much easier to observe in air-dried, Giemsa-stained material than in fixed, Papanicolaou-stained smears. In our experience, small cytoplasmic vacuoles may also be observed in pleural tumors (Figs. 26-13B,C, 26-14A). We have also observed these features in a case of a mesothelioma of tunica vaginalis testis (see below).

Figure 26-12 Malignant mesothelioma of the pleura in a 54-year-old woman without asbestos exposure. A. Two large papillary clusters known as “morulae.” **B.** A single large 3-dimensional papillary cluster in the same fluid. **C.** Markedly atypical mesothelial cells with

larger than normal nuclei and small nucleoli. *D.* Epithelial mesothelioma involving the diaphragm. The tumor was resected, and the patient survived disease-free for 5 years.

Rare Sites

Pericardium

Primary malignant mesothelial tumors of the pericardium are exceedingly rare and only a few such cases are on record (review in Warren, 2000). We have seen several cases, mainly in consultation. The **dominant symptom** in such patients is **recurrent pericardial effusion that may lead to tamponade**. The **cytologic presentation is identical to that of pleural effusions**, described above (Fig. 26-15). Although the possibility of cure is remote, the best therapeutic option is total pericardiectomy. It is of interest that **mesothelioma in situ** is readily observed on the mesothelial (inner) surface of the pericardium (Fig. 26-15D).

Ovary

These rare tumors have a histologic and cytologic presentation of carcinomatous mesothelioma, except for their **primary presentation on the ovarian surface** (Parmley and Woodruff, 1974; Nicosia and Nicosia, 1988; Clement et al, 1996). In a few personally observed tumors of ovary **with ascites**, the diagnosis of mesothelioma could be suggested on cytologic grounds and confirmed by histology (Fig. 26-16). The differential diagnosis in such cases includes serous cancers of ovary or of peritoneum. As discussed below, the level of cytologic abnormalities in such cases is significantly higher than in mesotheliomas.

As a rule, the **ovarian mesotheliomas do not invade the ovary, but envelop its surface. A mesothelioma in situ can be observed on the ovarian surface, confirming the diagnosis**. Primary ovarian mesotheliomas must be **differentiated from abdominal mesotheliomas enveloping the ovaries and other primary ovarian tumors of a similar configuration**, discussed in Chapter 16 (Lindeque et al, 1985; Clement et al, 1996). Of particular importance in the differential diagnosis are the **primary ovarian or extraovarian serous papillary carcinomas** that may mimic mesotheliomas in fluids (Dalrymple et al, 1989; Raju et al, 1989; Tauchi et al, 1996).

Attanoos and Gibbs (2000) described four patients with carcinomatous mesothelioma occurring **within the ovary**, without surface involvement. The identity and origin of such tumors clearly requires further scrutiny.

Tunica Vaginalis Testis

The first primary cytologic diagnosis of a malignant carcinomatous mesothelioma of tunica vaginalis testis was reported by Japko et al (1982). The cytologic presentation of hydrocele fluid in a 28-year-old man with a history of exposure to asbestos was a paradigm of this disease (Fig. 26-17A,D). Numerous **spherical, often overlapping, mulberry-shaped cell clusters** (morulae), composed of atypical cells of mesothelial type, were noted. Single **malignant cells of mesothelial type** with obvious nuclear abnormalities were also present. It may be noted that the **cytoplasm of the cancer cells contained numerous small perinuclear vacuoles**, in keeping with Boon's observations pertaining to malignant mesothelioma of peritoneal origin (see above). Numerous **calcified psammoma bodies** were present in some of the cell clusters.

Histologic examination documented papillary growth on the surface of the resected tumor (Fig. 26-17E). Transition of normal mesothelium to abnormal mesothelium was observed as was the presence of calcified bodies. Invasion of lymphatics was also observed. The tumor gave a positive immunoreaction with a monoclonal antibody to mesothelial cells, kindly provided by Dr. G. Singh of the University of Pittsburgh (Fig. 26-17F). On electron microscopic examination, numerous long surface microvilli were observed on tumor cells (Fig. 26-18). A case similar to ours was reported by Ahmed et al (1996). Ascoli et al (1996) reported a case of carcinomatous mesothelioma of tunica vaginalis testis in a patient who also had biphasic malignant mesothelioma of the pleura and a carcinomatous mesothelioma of the abdominal cavity. Attanoos and Gibbs (2000) described three patients with **carcinomatous mesotheliomas**

occurring within the testes without involvement of the tunica vaginalis. As commented above in reference to similar tumors of the ovary, the identity and origin of such tumors is puzzling. Plas et al (1998) noted that very few cases of mesothelioma of the tunica vaginalis are diagnosed preoperatively in an early stage with resulting poor prognosis in advanced tumors.

Unusual Cytologic Presentations

Spriggs and Grunze (1983) described three cases of **pleural mesothelioma** with foamy, macrophage-like cells and

P.968

vacuolated cells, similar to changes attributed by Boon et al to peritoneal lesions. We have also observed such cells in pleural mesotheliomas (see Fig. 26-13B). A case of a malignant pleural mesothelioma with macrophages and vacuolated **signet ring-type cells** was described by Gaffanti and Falen (1985). The presence of vacuolated cell forms may render the **differential diagnosis from metastatic cancer** (including the very rare **signet ring-type lymphomas**) very difficult. A malignant mesothelioma **mimicking squamous carcinoma** was described by Johnson and Edwards (2001). A malignant abdominal mesothelioma **mimicking mucinous carcinoma of stomach** was described by Cook et al (2000).

Figure 26-16 Mesothelioma of ovary. *A,B.* Clusters of typical cells of malignant mesothelium in ascitic fluid. *C.* Papillary proliferation on the surface of the ovary, typical of ovarian mesothelioma. *D.* The tumor focally infiltrated the surface of the ovary.

Gillespie et al (2001) and Reis-Filho et al (2002) described the cytologic features of **mesothelioma with deciduoid features**. In keeping with histology of this tumor, the dominant cells were large epithelial cells with eosinophilic cytoplasm and single or double large, pleomorphic nuclei with prominent nucleoli. In such rare cases when the precise cytologic diagnosis cannot be rendered, a surgical biopsy occasionally may be helpful. It must be stressed, however, that these are exceptional cases and that in most situations the cytologic presentation of carcinomatous mesothelioma is classical, as described above.

Another point of differential diagnosis pertains to **nodular histiocytic hyperplasia**, a benign nodular lesion of pleura composed of macrophages that may be accompanied by effusions. In **cell blocks** of such effusions, the spherical macrophages may form **irregularly shaped loose clusters** of cells with clear cytoplasm that may mimic clusters of mesothelial cells in **mesotheliomas or, for that matter, metastatic carcinomas** (Choi and Song, 2001). Naylor (2002) thought that the cell aggregates are bound together by bands of fibrin.

Ancillary Procedures in Diagnosis

Immunocytochemistry

With the introduction of immunologic techniques, large batteries of monoclonal and polyclonal antibodies were tested to refine the separation of carcinomatous mesotheliomas from other primary- or metastatic adenocarcinomas (summaries in Bedrossian, 1994; Roggli et al, 1992; Battifora and McCaughey, 1994; Leers et al, 1998; Ordoñez, 1999, 2003; Cury et al, 2000; Davidson et al, 2001; Carella et al, 2001; Miettinen and Sarlomo-Rikala, 2003, Attanoos et al, 2003). The issue is discussed at length in Chapter 45, but the dilemmas have not been solved. As an example of the problem, carcinoembryonic antigen (CEA) and monoclonal antibodies to epithelial membrane antigen (EMA) were reported

P.969

as expressed in metastatic tumors, but not in mesothelioma (Battifora and Kopinski, 1985; Dewar et al, 1987). However, Walz and Koch (1990) documented positive staining with EMA and CEA in 8 of 43 mesotheliomas. In a recent review of immunochemical reactions to keratin, p53, and epidermal membrane antigen, no significant differences were observed between benign epithelial proliferations and carcinomatous mesotheliomas. Miettinen and Sarlomo-Rikala (2003) observed a positive reaction to several "mesothelium specific" antibodies in several variants of bronchogenic carcinoma. A monoclonal antibody, allegedly specific for mesothelial cells (provided by Dr. G. Singh), has been successfully used by us in a case of a mesothelioma originating in the tunica vaginalis testis (Japko et al, 1982) (Fig. 26-19F), but its diagnostic value has not been further documented.

Figure 26-17 Mesothelioma of tunica vaginalis testis in a 28-year-old man, first diagnosed by cytology. *A.* Multiple complex papillary clusters of cells superimposed on each other. *B.* Higher magnification of one of the clusters showing a surface composed of large mesothelial cells. *C.* Cell-in-cell arrangement of atypical mesothelial cells. *D.* Papillary cluster with a large psammoma body. *E,F.* Various aspects of the mesothelioma, which is stained with immunoperoxidase-labeled antibody in *F*, believed to be specific for mesothelial cells. (Kindly provided by Dr. G. Singh, University of Pittsburgh.)

Lack of specificity of the available reagents is discussed once again in an elaborate study by Ordoñez (2003) who

P.970

tested a very large number of antibodies, none of which was either specifically positive or specifically negative for mesotheliomas. This author recommended that a panel of two “positive” markers, such as calretinin (see Fig. 26-11D) and cytokeratin 5/6, and two “negative” markers, such as CEA and MOC-31, offer the best diagnostic options.

Figure 26-18 Electron micrograph of tumor cells of mesothelium of tunica vaginalis testis showing numerous, often swollen microvilli on cell surfaces. The tumor cells were bound to each other by desmosomes. ($\times 12,400$.) (Japko L, et al. Malignant mesothelioma of the tunica vaginalis testis; report of first case with preoperative diagnosis. *Cancer* 49:119-127, 1982.)

Figure 26-19 Sarcomatous mesotheliomas. Two examples of sarcomatous mesothelioma with spindly cells obtained on aspiration biopsy. In *A*, the cells form a long sheet whereas in *C*, they appear singly. *B, D*. Corresponding tissue patterns.

In my experience, the **simplest procedure** differentiating carcinomatous mesothelioma from other malignant tumors is the inexpensive **mucicarmine stain**, which is **negative in mesotheliomas**, but often positive in pulmonary adenocarcinoma, or adenocarcinomas

metastatic from a distant site. Regardless of the technique used, the availability of cell blocks is very helpful in such ancillary studies.

Ultrastructural studies may disclose differences between primary pulmonary adenocarcinoma and carcinomatous mesothelioma. Features of Clara cell or pneumocytes type II (see Chap. 19) are not seen in mesotheliomas. On the other hand, cells of mesotheliomas are often provided with abundant, **long anastomosing surface microvilli of irregular configuration** (see Figs. 26-1, 26-18) that may make contact with collagen fibers across the defective basement membrane (Dewar et al, 1987). The microvilli on the surface of other cancer cells are usually much shorter.

Cytogenetics

Losses of the short arm of chromosome 1 (**del.1p**), short arm of chromosome 3 (**del.3p**), and long arm of chromosome 22 (**del.22q**) appear to be fairly constant cytogenetic abnormalities in carcinomatous mesothelioma (Gibas et al, 1986; Bello et al, 1987; Flejter et al, 1989). Losses of the long arm of chromosome 6 (**del.6q**) and short arm of chromosome 9 (**del.9p**) were reported by Taguchi et al (1993).

P.971

Cytogenetic analysis of fluids in suspected cases of carcinomatous mesotheliomas yielded excellent results and was particularly helpful in situations where the cytologic findings were equivocal (Granados et al, 1994).

Cytology of Benign Tumors of Mesothelium

Papillary Mesothelioma

In 1976, Becker et al reported a case of “**mesothelial papilloma**” diagnosed in pericardial fluid in a 34-year-old male who did well postoperatively. There is little doubt that today this tumor would be classified as a **papillary mesothelioma**. Becker et al reported the **cytologic findings** as **mimicking carcinomatous mesothelioma** and the illustrations confirm it. There are two other case reports of cytology of this uncommon tumor known to us. Jayaram and Ashok (1988) reported the presence of papillary clusters of round tumor cells with eccentric, but otherwise unremarkable nuclei in peritoneal fluid in a young woman. The treated patient was free of disease 5 years later. Haba et al (2003) described another case of peritoneal tumor in a 48-year-old woman and reported similar findings. It is quite evident that the cytologic presentation of papillary mesothelioma may mimic carcinomatous mesothelioma.

Multicystic Peritoneal Mesothelioma

In a case reported by Baddoura and Varma (1990), **large sheets of benign mesothelial cells were observed in fluid drained from the cysts**. After surgical removal of the tumor, the patient remained well for 7 years after the onset of symptoms. Another case, with very similar cytologic findings, was reported by Devaney et al (1992). Long-term survival has been noted in other patients (Kampschoer et al, 1992).

Fibrosarcomatous Mesotheliomas

The relationship of fibrosarcomatous mesotheliomas to asbestosis is questionable. The tumors are often discovered on routine chest x-ray or because of respiratory symptoms or chest pain. Effusion as the first manifestation of disease is uncommon, contrary to carcinomatous mesothelioma. Personal experience suggests that the results of treatment of fibrosarcomatous

mesothelioma are probably much better if the tumor can be removed by surgical procedures.

Histology

These vary in configuration from a **well-differentiated fibrous tumor resembling a fibroma** to tumors resembling **fibrosarcomas**. Bundles of **elongated, malignant, but sometimes deceptively benign-looking spindly cells**, are usually observed (see Fig. 26-19B,D). Some of the tumors may have a less compact structure with intervening areas of loose connective tissue (Fig. 26-20B). Islands of benign mesothelium are sometimes trapped within such tumors. In contrast to carcinomatous mesothelioma, we have never observed a mesothelioma in situ associated with one of the fibrous tumors. In our experience, the **prognosis** of the spindly cell tumors, most of which occur in the pleura, is unpredictable. Some of the seemingly orderly tumors metastasized widely (see Fig. 26-19) while other tumors with a more ominous histologic pattern were apparently cured by surgical excision.

As has been emphasized above, this type of tumor is **almost never associated with a primary effusion**. Furthermore, if effusion does occur later in the course of the disease, it **rarely contains cancer cells**. In most instances, the diagnosis of sarcomatous mesothelioma has been established on **direct fine needle aspiration (FNA)** of pleural lesions or on tissue biopsy. A spindly cell **malignant tumor of the diaphragm** in an asbestos worker has been reported as a **leiomyosarcoma** by Dionne et al (1976).

Cytology

In material **aspirated directly from the sarcomatous mesotheliomas**, there is usually none of the diagnostic difficulty encountered with carcinomatous mesothelioma. However, the **configuration of the spindly tumor cells may vary** from quiescent-looking fibroblast-like cells (see Fig. 26-19A,C) to spindly, clearly malignant cells with large, hyperchromatic nuclei (see Fig. 26-20A,C). The **spindly cancer cells often form sheets or whorls**.

Solitary Fibrous Pleural Tumors

It is still a matter for debate whether **circumscribed, solitary fibrous pleural tumors, some of which may display a histologic pattern of sarcoma, are benign or malignant**. Briselli et al (1981) reviewed a large series of those cases. The mortality was 12%, regardless of histologic pattern. **Effusions are extremely rare as the first manifestation of these tumors**. It is of note, though, that **hypoglycemia** may be the primary clinical event in about 4% of these patients (summary in Roncalli et al, 1988).

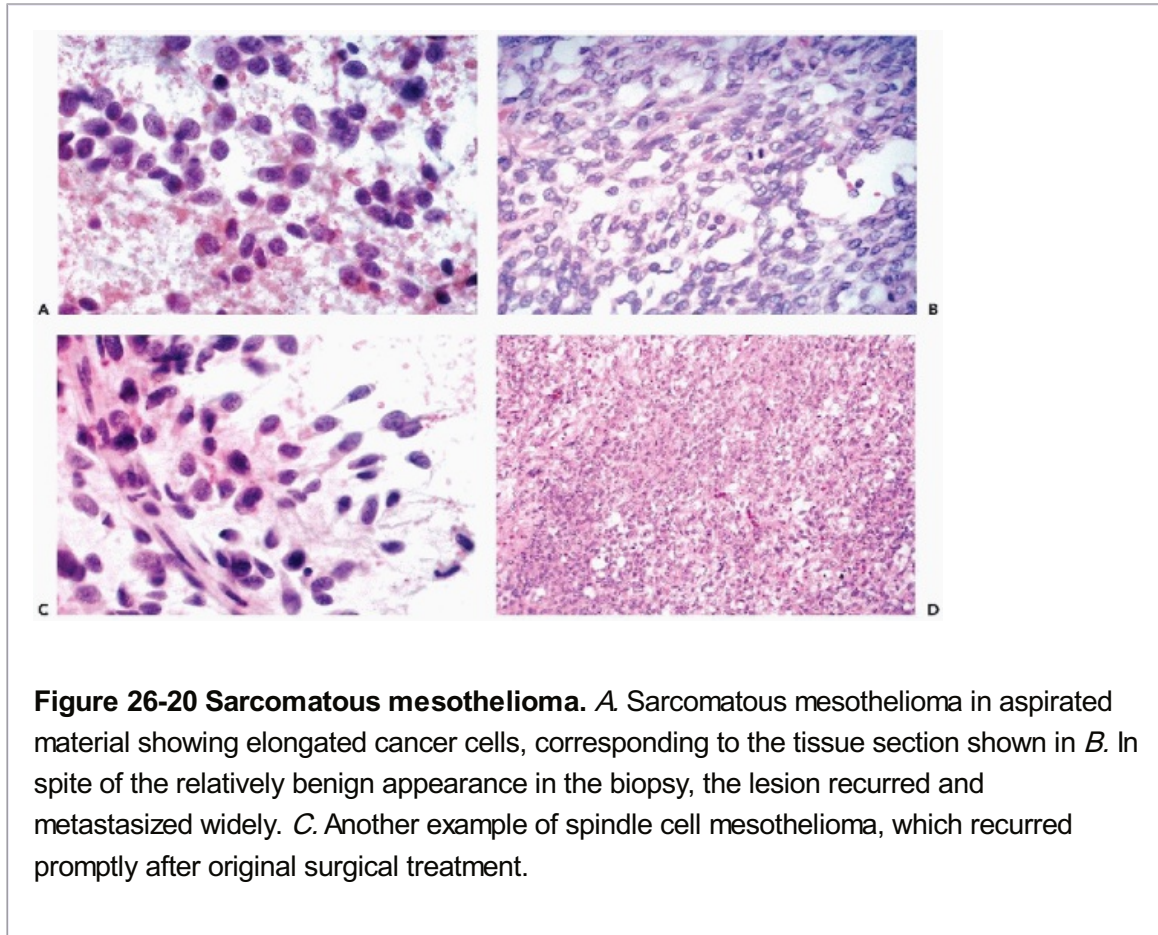

The presence of **elongated, fibroblast-like cells** characterized the tumors. Immunocytochemical reaction to **antibody CD34** was reported as helpful in establishing the specific diagnosis (Apple et al, 1997; Ali et al, 1997; Waynand et al, 1998; Drachenberg et al, 1998). Ali et al observed morphologic differences between benign and malignant tumors. The malignant tumors had a larger number of elongated cells with greater nuclear pleomorphism and prominent nucleoli. In the hands of these investigators, the CD34 feature was not always expressed by tumor cells. In our experience, the **cytologic separation of the solitary fibrous tumors of the pleura from fibrosarcomatous mesotheliomas is morphologically very difficult** (see Fig. 26-19). However, the clinical and roentgenologic presentation may help in further classification of the aspirate. Because in suitable patients most of these lesions will be treated by a surgical procedure, **perhaps the most important role of cytology in the assessment of these tumors is to decide that the lesion is not a metastatic tumor or a carcinomatous mesothelioma, and thus clear the way for a surgical exploration**.

Mixed Type of Malignant Mesotheliomas

This rather uncommon variety of mesotheliomas **resembles a biphasic malignant synovioma**. These tumors are composed

P.972

of **solid sheets of small, spindly cells with gland-like cavities lined by cuboidal cells** (see Fig. 26-9D). In my opinion, this is possibly the only primary tumor of mesothelial surfaces in which a simultaneous participation of the epithelial and the connective tissue components may be reasonably proposed.

With this tumor type, **effusions containing malignant cells have been observed**. The cancer cells are usually **spindly in configuration and are often accompanied by markedly atypical or clearly malignant, mesothelial cells**. Admittedly, the specific diagnosis of this uncommon type of malignant mesothelioma in effusions is difficult but the malignant nature of the effusion is usually quite evident.

Other Primary Malignant Tumor of Mesothelial Surfaces

Intraabdominal (and Intrapleural) Desmoplastic Small Cell Tumors

This uncommon tumor has been fairly recently recognized as a **lethal form of small cell cancer**, affecting **mainly, but not exclusively, young males in their teens or early 20s** (Gerald et al, 1991). Although initially thought to be a neoplasm confined to the abdomen, **similar tumors have been observed in other locations, such as the pleura** (Wolf et al, 1999). **Ascites or pleural effusions are often the first manifestations of these tumors**

and, therefore, their cytologic presentation is of significant clinical value.

Histology

The tumor is composed of **small cancer cells arranged in irregularly shaped nests**, that are separated from each other by **broad bands of connective tissue**. The tumor cells **resemble small epithelial cells**, have **scanty but clearly evident cytoplasm**, **large nuclei with moderate-size nucleoli**. Intense **mitotic activity** with many atypical mitotic figures is evident. Foci of tumor necrosis are commonly observed. Lymphocytic infiltrate is often seen (Fig. 26-21). Variants of this tumor with little desmoplasia have been described (Dorsey et al, 1996). The tumors often but not always show a **chromosomal translocation**, affecting a break point on **chromosome 11** (11p13), that may be translocated to chromosomes 22 [t 11;22 (p13q13)] or 17 (t 11;17) resulting in a **chimeric transcript** known as EWS-WTI (summary in el-Kattan et al, 1995). The translocation links this tumor with poorly differentiated childhood tumors, globally known as “**small round blue cell tumors**.” Still, **the size of the cancer cells and their cytoplasmic area in the desmoplastic**

P.973

tumors is much larger than in the small cell tumors of childhood. Further, the desmoplastic tumors give a **positive staining reaction to cytokeratin and desmin**, a combination that is rarely, if ever, observed in the small cell tumors of childhood, which are discussed below.

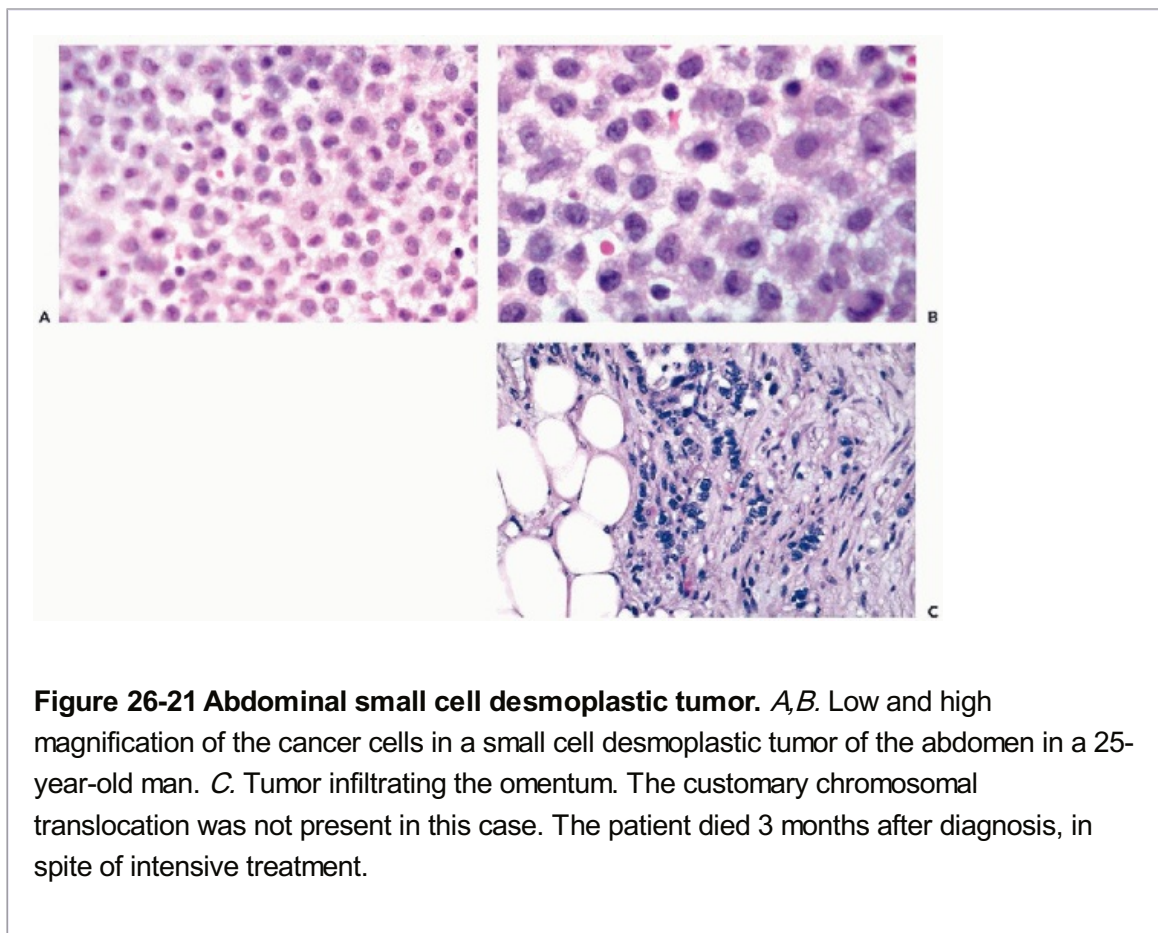

Figure 26-21 Abdominal small cell desmoplastic tumor. *A,B.* Low and high magnification of the cancer cells in a small cell desmoplastic tumor of the abdomen in a 25-year-old man. *C.* Tumor infiltrating the omentum. The customary chromosomal translocation was not present in this case. The patient died 3 months after diagnosis, in spite of intensive treatment.

Cytology

The tumors have been studied in **aspiration biopsy (FNA)** material and in ascitic and pleural fluids. In FNA smears, el-Kattan et al (1995) described **small tumor cells with uniform**

nuclear structure and scanty, but visible cytoplasm. Ali et al (1998) reported on two such tumors in women and observed the presence of **small cancer cells with very scanty cytoplasm and fragments of connective tissue stroma in the aspirate.** Neither group of authors recognized specific cell features characteristic of the tumor and offered a wide spectrum of differential diagnoses with other small-cell tumors.

Bian et al (1993) described the findings in smears and cell blocks of **pleural fluid** in a male patient with the tumor located in the pleura. The tumor cells formed **three-dimensional clusters.** The tumor cells, best seen in the cell block, had **clearly abnormal, irregular nuclei with extensive mitotic activity.** Dutt et al (2001) also described the ascitic fluid cytology of a desmoplastic small cell tumor of the abdomen as **mimicking adenocarcinoma** because of formation of three-dimensional papillary clusters.

Our own limited experience matches that of Bian et al and Dutt et al. The **tumors shed clusters of small cancer cells with clearly visible cytoplasm that have a much greater similarity to an epithelial tumor than the “small blue round cell tumors” of childhood** (Fig. 26-21). In cells blocks, **positive staining for keratin and desmin facilitates the classification** of the tumor. When **combined with clinical information,** the diagnosis of this tumor in cytologic samples appears possible. At least the tumor should be considered in the differential diagnosis of abdominal and pleural neoplasms in young adults.

Extraovarian Peritoneal Serous Papillary Carcinomas and Related Lesions

These uncommon tumors of women may produce **ascites** wherein the cancer cells can be readily recognized (Dalrymple et al, 1989; Raju et al, 1989; Tauchi et al, 1996; see discussion in Chap. 16). The **cytologic presentation of these tumors cannot be distinguished from that of metastatic serous carcinoma or borderline tumors of the ovary,** discussed in Chapter 16 and below. The **differential diagnosis includes other metastatic tumors of similar configuration, such as the uncommon uterine serous carcinoma** (described in Chap. 13) **and, more remotely, mesotheliomas.** In effusions, the **cells of primary serous carcinomas and borderline tumors form large flat cohesive sheets of cancer cells that do not resemble the “morulae” of mesothelioma** (Fig. 26-22). Also, the relatively few single

P.974

cancer cells in such tumors do not resemble mesothelial cells. Still, the differential diagnosis can be difficult and knowledge of clinical data is essential to prevent errors.

Figure 26-22 Primary peritoneal serous carcinoma, no ovarian involvement. *A,B.* The very large papillary clusters of cells in ascitic fluid. *C.* One of the clusters under high power showing the makeup of the tumor of large but monotonous cancer cells. *D.* A section of the omentum showing infiltrating tumor.

Pleural Thymoma

We observed a case of primary thymoma located in the pleura in a middle aged woman with pleural effusion who was thought clinically to have a mesothelioma. The pleural fluid was not informative but a transcutaneous aspiration biopsy disclosed a **classical pattern of thymoma** composed of lymphocytes and epithelial cells. The diagnosis was confirmed on surgical specimen. The mediastinal thymus was identified on surgery and it was not involved. For further discussion of cytology of thymoma, see Chapter 37.

Squamous Carcinoma

Through the courtesy of the late Dr. M. Wilson Toll, we had the opportunity to observe a **primary squamous carcinoma of the pleura** developing in a tuberculous patient with an induced pneumothorax of many years' duration. In the pleural effusions, the cytologic presentation was that of a **classic keratinizing squamous carcinoma with formation of squamous "pearls" and anucleated squames**. At the time of autopsy, the tumor was shown to be derived from the squamous lining of the cavity created by pneumothorax. There was evidence of residual active tuberculosis. The tumor was present in the pleura and had metastasized to the heart and liver (Fig. 26-23).

Primary Angiosarcoma of Pleura

This very rare tumor was observed in a 60-year-old man who was free of AIDS and showed no evidence of Kaposi's sarcoma. In the **pleural fluid**, there were obviously **malignant, elongated cells** with large, hyperchromatic nuclei. The initial diagnosis of "malignant tumor, possibly a sarcoma" was confirmed on pleural biopsies and subsequent autopsy. The tumor formed vascular channels in fibrosed pleura and showed focal growth as a spindle cell sarcoma (Fig. 26-24). The tumor cells were negative for keratin but positive for factor VIII, confirming the

vascular nature of the neoplasm that metastasized widely shortly after the diagnosis was established.

Primary Body Cavity Malignant Lymphomas in AIDS

Primary malignant lymphomas of serous membranes (**body cavity lymphomas**), **associated with effusions**, have been recognized as a specific entity, associated with AIDS (Knowles et al, 1989). **Herpesvirus type 8, first identified in Kaposi's sarcoma** in AIDS patients, was identified in these effusions (Chang et al, 1994; Cesarman et al, 1995). In some patients, the presence of **Epstein-Barr virus (EBV)** can also

P.975

be recognized (Knowles et al, 1989; Mansour et al, 1998). An antibody (LN53) that recognizes herpesvirus type 8 may serve to identify this type of lymphoma (Dupin et al, 1999).

By definition, the **first presentation of these tumors is an effusion** wherein cancer cells can be recognized. The clinical presentation and cytologic features of effusions are discussed with other lymphomas further on in this chapter.

Primary Cardiac Lymphomas

Primary lymphoma of the heart is virtually always accompanied by a **pericardial effusion, wherein the cancer cells can be recognized** (Curtsinger et al, 1989; Castelli et al, 1989; Chao et al, 1995). The disease can occur in **heart transplant patients** and its morphologic presentation is identical to that of a metastatic malignant lymphoma, described below in this

chapter.

METASTATIC TUMORS

The principles of recognition of malignant cells in effusions and their classification as to tumor type were presented in the opening pages of this chapter. In this segment, the cytologic presentation of specific tumor types related to organs of origin will be discussed.

Mammary Carcinoma

The histology of the principal types of mammary carcinoma is summarized in Chapter 29.

Metastatic mammary carcinoma is, by far, the most **common tumor** associated with **pleural effusions in women**. It may also cause **ascites** and, occasionally, **pericardial effusions**. In most patients, there is a history of treated mammary carcinoma. However, there are rare instances when the primary site of cancer is unknown and the identification of the **mammary origin of the tumor** may be of **diagnostic and therapeutic value**. The cytologic confirmation of the mammary origin may also be of **prognostic value** because, in many instances, such effusions may be controlled by hormonal manipulation, chemotherapy, and radiotherapy.

The **cytologic presentation of mammary carcinoma depends to a significant extent on histologic tumor type** and is quite variable. On **first tap, the background of the smears is usually clean and free of inflammatory cells**. On subsequent taps, there is often evidence of inflammation. In some patients, there is a **massive proliferation of cancer cells**,

P.976

suggestive of tissue culture pattern (Fig. 26-25). The clinical significance of this observation has not been established.

Figure 26-24 Primary angiosarcoma of pleura. *A,B.* Elongated large cancer cells in pleural fluid. *C.* Vascular channels in the pleura of this patient at autopsy. *D.* Cell pattern of the tumor corresponding to the cytologic abnormalities shown in *A* and *B*.

Cell size of mammary cancer cells may **vary**, with most tumors shedding **medium size** cells.

The **larger tumor cells usually correspond to infiltrating duct carcinomas** composed of large cells, and the less common **medullary carcinomas**. The metastases from infiltrating duct carcinoma with fibrous stroma (**scirrhous carcinoma**) and **colloid carcinomas**, usually produce **medium-sized** cancer cells. **Papillary carcinomas** rarely result in effusions.

Effusions caused by infiltrating lobular carcinomas usually contain **small cancer cells**, which may be mucus-producing and resemble small signet ring cells with cytoplasmic mucous inclusions (see below).

Breast carcinomas of the **medium- or large-cell type** are easily recognized as malignant in effusions because the cells have the **classic features of metastatic adenocarcinomas, described in the opening pages of this chapter**. In smears or liquid preparations, the **cancer cells** occur singly, but often form clusters of various sizes. The most characteristic feature is the presence of large, **three-dimensional clusters of round, oval, or irregular configuration**, wherein the cells are superimposed on each other (Fig. 26-26). In **histologic sections of cell blocks**, the large clusters often, but not always, have a **glandular or tubular configuration with a central lumen**. For this reason, some observers refer to such cell clusters as “**spheroids**” or “**hollow spheres**” (see Fig. 26-4C,D). Another common arrangement of mammary cancer cells is in a **single file** (Fig. 26-27), that may occur in any type of breast cancer, but is particularly valuable in the diagnosis of lobular carcinoma (see below).

In smears, single cancer cells of metastatic **duct carcinomas** are often of similar sizes but there are many exceptions to this rule, particularly if the cells are multinucleated. The **cytoplasm** may be either homogeneous or containing **vacuoles** of various sizes (Fig 26-27A). The vacuoles often contain **mucins**. Surface microvilli or blebs may be occasionally observed, particularly in air-dried smears. The **nuclei** are often eccentric in location. The **nuclear features** of cancer are usually classic and comprise **nuclear enlargement, granularity of the chromatin, prominent nucleoli and abnormal mitoses** (Figs. 26-26, 26-27). The degree of **hyperchromasia is variable**. **Sex chromatin bodies**, single or multiple, may be readily identified in some of the cancer cells (Fig. 26-27B). **The presence of multiple sex chromatin bodies practically assures the diagnosis of cancer, most likely of mammary origin, regardless of other cell features** (for further discussion of prognostic significance of sex chromatin bodies in breast cancer, see Chap. 29).

Cells of mammary cancers of **small size** usually reflect an underlying **infiltrating duct carcinoma composed of small cells or a lobular carcinoma** and are easily recognized in effusions if they form a “tissue culture” pattern or **large spherical clusters** similar to those described above. Such tumor cells may also form **long chains** of cancer cells **arranged in a single file** and, in my experience, are more often observed in carcinoma of the breast than in any other tumor corresponding to the arrangement of cells in tissues (Figs. 26-27C,D, 26-28). In such chains, the recognition of **nuclear abnormalities**, such as **nuclear enlargement, hyperchromasia, or a peculiar rectangular configuration** without molding, is usually easy (see Fig. 26-28B). The **rectangular nuclei** appear to be uniquely **characteristic of mammary carcinoma cells forming chains**. Mesothelial cells may occasionally form short chains that very rarely are composed of more than three to four cells with normal nuclei (see Chap. 25). Cancer cells of other primary origins than breast, notably **metastatic ovarian carcinoma**, may also form a chain-like arrangement, but the component cells are usually larger than in breast cancer, with the **exception of oat cell carcinoma** (see below).

Figure 26-25 Metastatic mammary carcinoma in pleural fluid. *A,C.* Marked proliferation of cancer cells in the pleural fluid corresponding to “tissue culture pattern.” *B,D.* Corresponding primary mammary cancer.

Figure 26-26 Breast cancer in effusions. Another example of breast cancer growing in an effusion. *A.* Note a large vacuolated cancer cell. *B.* Small cluster of cancer cells. *C.* At high magnification, there is a large cluster of cancer cells; a mitotic figure is clearly visible. *D.* Mammary carcinoma of ductal type corresponding to the cytologic findings shown in *A-C*.

Figure 26-27 Various aspects of mammary carcinoma in effusions. *A.* Several large cancer cells with vacuolated cytoplasm. *B.* High magnification showing a cancer cell with three Barr bodies (*arrows*). *C.* Single file arrangement of cancer cells corresponding to infiltrating duct carcinoma shown in *D.*

Spriggs and Jerrome (1975) were the first to point out another **characteristic feature of mammary cancer cells**, notably their **configuration in the form of small- or medium-sized signet ring-like cells** with the nucleus pushed to the periphery. The cytoplasm of these cells is distended by large, **mucus-containing vacuoles with a central eosinophilic inclusion**. The inclusion was shown by electron microscopy to be an amorphous mass, later shown to be constituted by **inspissated mucus**, located within a cytoplasmic space lined by microvilli (Fig. 26-29). In light microscopy, the **single central intracytoplasmic “inclusions”** are readily seen and give a **strongly positive stain with mucicarmine** (Fig. 26-28D). In air-dried, May-Grün-wald-Giemsa (MGG)-stained aspiration smears, the **mucus inclusions stain purple or magenta** and hence the name of **“magenta cells”** that some observers have applied to these cells. Other observers have named such cells **“target cells.”** Recently, Kumar et al (2000) claimed that similar cytoplasmic inclusions may occur in adenocarcinomas of other primary origin. While I cannot rule out this possibility, in my experience this appearance of cancer cells is **uniquely characteristic of primary or metastatic mammary carcinoma, sometimes of ductal but usually of lobular type** (see also Chap. 29).

Exceptional cytologic patterns of mammary carcinoma may occur in metastatic **colloid (gelatinous) carcinomas**, where the effusion may contain mucus and tightly knit clusters of cancer cells, sometimes forming rosettes (Fig. 26-30A,B). In a very rare case of **basaloid carcinoma of the breast**, we observed large clusters of small cancer cells, similar to cells of oat cell carcinoma (see Chap. 29).

Figure 26-28 Lobular carcinoma in effusions. *A-C.* Documented case of infiltrating lobular carcinoma in pericardial fluid. The cell arrangement in single file with flattening of the nuclei is characteristic of this disease. *B.* Oil immersion. *C.* Histologic section of the primary lobular carcinoma corresponding to cells shown in *A* and *B*. *D.* Mucicarmine stain to demonstrate the presence of intracytoplasmic spherical vacuoles with central inclusions, forming so-called "target cells" in ascitic fluid.

The **greatest diagnostic difficulty** with breast cancer in fluids occurs when single, dispersed cancer cells cannot readily be distinguished by size from mesothelial cells and macrophages. In such cases, **a very careful analysis of morphologic details is required**. The easiest task is the **search for mitoses** which, if present, strongly suggest that the cells are malignant. The search for **nuclear abnormalities**, notably coarse granulation of chromatin, the presence of **enlarged nucleoli**, and excessive number of sex chromatin bodies, usually confirm the diagnosis. Another diagnostic problem may occur if mammary carcinoma is synchronous with, or followed by, **another epithelial tumor, particularly ovarian carcinoma, as it may happen in patients with a mutation of breast cancer genes 1 or 2** (see discussion in Chaps. 15 and 29). In such cases, in the absence of morphologic clues, deciding whether the effusion is caused by mammary or other adenocarcinoma may be exceedingly difficult without accurate clinical data. **Breast cancer is more likely to cause a pleural effusion before ascites, whereas the opposite is true for ovarian and other abdominal cancers.**

Mammary cancer cells may also be tested for **nuclear estrogen receptor molecules**. Although the reaction **is not absolutely specific**, because other metastatic tumors, such as **endometrial or ovarian carcinomas** may also contain estrogen receptors, it is sometimes a useful adjunct to morphologic diagnosis. The specificity of **HER2/neu** gene expression in mammary carcinoma to my knowledge has not been tested in effusions.

Prognostic significance of cytologic patterns of mammary carcinoma in effusions of women was studied by Towers and Melamed (1979), Wiley and Von Roenn (1990) and by Dieterich et al (1994). Towers and Melamed studied the **cellularity of the smears**, the presence of **tumor cell clusters**, the frequency of **mitoses**, and the presence of **lymphocytes** as an index of the patient's immune reaction to the tumor and **failed to attribute any prognostic significance to any of the four factors studied**. Quite contrary to these findings, the presence of **spherical**

(papillary) cell clusters in effusions (named “**morulae**” or “**hollow spheres**” by Wiley and Von Roenn and “**spheroids**” by Dieterich et al), particularly if the cancer cells contain **estrogen receptors**, was apparently associated with a **better survival** when compared with women with less well-organized cancer cells in effusions. Besides the presence of the “spheroids,” Dieterich et al also observed that **low levels of nuclear atypia and low mitotic rate** are favorable survival factors and recommended that these features should be reported.

P.980

Thus, there is a major difference between the Towers and Melamed observations from 1979 and the two groups of authors writing over a decade later. It may be that the papers by Wiley and Von Roenn (1990) and by Dieterich et al (1994) reflect an improvement in therapy rather than other factors.

Figure 26-29 Pleural fluid: metastatic mammary carcinoma. Electron micrograph of a cell showing an intracytoplasmic space lined by microvilli. Within the space a round, dense inclusion gives a positive stain for mucus. This appearance, both in light and electron microscopy, is very characteristic of mammary carcinoma, usually of lobular type. (Spriggs A, Jerrome DW. Intracellular mucous inclusions: A feature of malignant cells in the serous cavities, particularly due to carcinoma of the breast. J Clin Pathol 28:929-936, 1975)

Male Breast Cancer

Effusions caused by metastatic **mammary carcinoma in males** are extremely rare. Four such cases were mentioned by Sears and Hajdu (1987). In a personally observed case, the cells in the pleural effusion were of large-cell type and could not be differentiated from duct carcinomas in women (Fig. 26-31).

Bronchogenic Carcinoma

For discussion of principal histologic types of bronchogenic carcinoma, see Chapter 20.

Lung cancer is the most frequently observed cause of

P.981

pleural effusions caused by malignant disease in men, although a recent rapid increase of this disease in women has been documented (see Chap. 20). Pericardial effusions and ascites associated with lung cancer are much less frequent. The cytologic presentation depends on tumor type.

Keratinizing Squamous Carcinoma

The cytologic presentation of a primary squamous carcinoma in effusions was described above (see Fig. 26-23). The finding of **squamous cells or “pearls” or of anucleated squamiae is diagnostic of the disease, even in the absence of nuclear abnormalities** (Fig. 26-32A-C). As discussed above, this tumor type is relatively rare in effusions, presumably because only viable cells survive and these have little tendency to keratin formation. Hoda et al (1998) described four cases of squamous lung cancer **metastatic to the pericardium**, resulting in cardiac tamponade in two patients and progressive heart failure in two others (Fig. 26-32C). The cytologic findings are the same when **squamous cancer is primary in the larynx or esophagus**. It is of interest that **gastric squamous carcinomas** may occur **in horses** and metastasize to the abdominal cavity, causing ascites. Through the courtesy of Dr. Jeffie Roszell of Tulsa, OK, we were able to examine the cell sediment in one such case and found remarkable similarity between the human and equine tumor presentation (Fig. 26-33).

Poorly Differentiated Squamous (Epidermoid) Carcinoma, Large-Cell Type

Marked cytoplasmic eosinophilia, as evidence of keratin formation that is helpful in identifying this tumor type in sputum is rarely **evident in fluids**. The cytoplasm of the cancer cells is, for the most part, thin, delicate, and transparent, and the **nuclei are large**, usually (but not always) **hyperchromatic**, and often display **large nucleoli**. The cells occur singly or in small clusters (Fig. 26-32). The diagnosis of a malignant tumor is usually easy but the exact **identification of tumor type in fluids is rarely possible, except occasionally in cell blocks** containing fragments of tumor.

Adenocarcinoma

This has become, by far, the most common type of lung cancer in effusions. It is characterized by **large cancer cells, occurring singly but often forming multilayered clusters**, sometimes with a papillary configuration, similar to clusters observed and described in other metastatic adenocarcinomas (see Fig. 26-32E). The tumor cells have no distinguishing features, except in the very rare cases when the tumor cells assume a **cuboidal or columnar configuration with**

P.982

one flat surface, suggestive of bronchial cell origin. The flat surface mimics the cilia-bearing terminal plate but cilia are not seen in light microscopy (Fig. 26-34). The nuclei have very **large nucleoli** and are usually somewhat less hyperchromatic than cells of epidermoid carcinoma. However, there remains a group of **poorly differentiated adenocarcinomas** which can easily be recognized as malignant but fail to display any of the features that make the recognition of tumor type possible. **Psammoma bodies** can sometimes be observed in effusions. In questionable cases, positive immunostaining for **thyroid transcription factor (TTF1)** may help in identifying the pulmonary origin of the tumor (Hecht et al, 2001). The differentiation of mesothelioma from peripheral pulmonary adenocarcinoma was discussed above.

Figure 26-32 Metastatic cancers of various types in pleural effusions. *A-C.* Examples of metastatic squamous carcinoma in pleural fluid from primary esophagus cancer (*A*) and from a primary lung cancer (*B*) shown in *C*. *D.* Poorly differentiated squamous carcinoma in pericardial fluid. *E.* Pulmonary adenocarcinoma (bronchioloalveolar carcinoma) in pleural fluid.

Oat Cell Carcinoma

Salhadin et al (1976), using fixed material stained with Papanicolaou stain, and Spriggs and Boddington (1976), using air-dried smears and May-Grünwald or Giemsa stain, nearly simultaneously reported on the specificity of the cytologic presentation of this tumor type in effusions. The **cancer cells are small, with very scanty cytoplasm**, usually forming small **clusters** of variable size. Although most cancer cells are approximately spherical, elongated cells may also be noted. **The nuclei are markedly hyperchromatic and**

P.983

the nucleoli are usually absent. Cell-in-cell configuration may occur (Fig. 26-35).

Figure 26-33 Ascitic fluid: metastatic squamous carcinoma of stomach in a horse.

A,B. Extremely well-differentiated squamous cancer cells. *C.* Metastatic, very well-differentiated squamous carcinoma in omentum. (Courtesy of Dr. Jeffie Roszell, Tulsa, OK.)

Perhaps the most **characteristic feature** of cells of oat cell carcinoma in effusions **is the formation of short chains made up of flattened cancer cells of various sizes**. These resemble a **pile of coins** of various denominations or a string of flat beads. Salhadin et al (1976) compared this presentation to the **arrangement of vertebrae** in spinal column, a most appropriate comparison (Fig. 26-35C). This arrangement of cells of oat cell carcinoma is somewhat similar to the single files observed in **small-cell mammary carcinoma**. Cytologically, the two tumors may be confused. However, the configuration of the nuclei and mucus production in mammary carcinoma separate it from oat cell carcinoma. In debatable cases, clinical history may shed light on the identity of the tumor.

Figure 26-34 Pleural fluid: metastatic bronchogenic adenocarcinoma (man, aged 60). *A*. Abundant growth of cancer cells forming tissue culture pattern. *B*. Note extraordinary resemblance of a metastatic malignant cell to bronchial epithelial cells. Note a terminal plate and, possibly, cilia on one surface. The nuclear abnormalities, especially the huge nucleoli, are clearly those of cancer. *C, D*. Other details of malignant cells: a cell-in-cell arrangement (*C*), and an atypical mitosis with chromosomal lag (*D*). Compare *C* with cell-in-cell arrangement of mesothelial cells in cirrhosis, shown in Figure 25-31*A*. (*B-D*: High magnification.)

Another important point of differential diagnosis is **malignant lymphomas**, which may also shed small cancer cells. As discussed in detail below, **malignant lymphomas do not form structured cell clusters and the configuration of the nuclei is quite different**. Further, **visible nucleoli, which are generally absent in oat cell carcinoma, are common in lymphomas**.

Chhieng et al (2001) and Wu et al (2003) noted that

P.984

positive immunostaining for chromogranin A and thyroid transcription factor (TTF1) were useful in differentiating oat cell carcinomas from other small cell tumors in effusions. Oat cell carcinoma is a tumor of adults. Thus, **age separates it from malignant tumors of childhood** composed of small cells that may sometimes have a somewhat similar cytologic presentation in fluids, as discussed below.

Figure 26-35 Oat cell carcinoma in pleural effusions. *A, B*. Disorderly clusters of very small cancer cells. *C*. Classical presentation of this tumor at high magnification in the form of a chain of cells, similar to a string of vertebrae. *D*. The tissue section of the tumor corresponding to *A-C*.

For discussion of pathology of these tumors, see Chapter 15.

Following breast and lung cancer, ovarian cancer is the most frequent metastatic malignant tumor in women that gives rise to effusions, usually **ascites**. **Pleural and, exceedingly rarely, pericardial effusions**, may occur but are usually **secondary to ascites** or other evidence of tumor spread beyond the abdominal cavity. The exact **identification of ovarian tumor type in effusions may be possible in some cases**, although in most women a histologic diagnosis of tumor type is available.

Serous Type of Ovarian or Extraovarian Carcinoma

Cytology of **primary serous carcinoma** of the peritoneum is discussed above (see Fig. 26-22).

The cytological presentation of **metastatic serous carcinoma** is usually less dramatic. In fluids, the pattern is that of a **papillary adenocarcinoma made up of large cells**, often accompanied by **psammoma bodies that may be either incorporated into cell clusters or be isolated** (Figs. 26-36, 26-37A,B). Surprisingly, in some of these tumors, the cytoplasm of cancer cells may show large vacuoles (Fig. 26-37C,D). This presentation is usually sufficiently characteristic **in ascitic fluid** to allow for **specific diagnosis of serous carcinoma** but does not differentiate between **ovarian or extraovarian (peritoneal) origin**. In the **pleural fluid**, the differential diagnosis includes **bronchogenic carcinoma, carcinomatous mesothelioma, mammary carcinoma** composed of large cells, and, **rarely, adenocarcinomas of other origins (endometrium, kidney)**, all of which may have a similar cytologic configuration and occasionally form rare, single psammoma bodies. The presence of **more than one psammoma body in a tumor composed of large cells usually speaks in favor of ovarian cancer**. Another metastatic tumor that may form numerous psammoma bodies in **pleural effusions** is **papillary thyroid carcinoma** (see Fig. 26-43C). However, in this tumor, the cell clusters are composed of much smaller cells and the cells display other features, such as the **intranuclear cytoplasmic inclusions**, that allow for an easy differential diagnosis (see below). So far, we have never observed thyroid cancer in

P.985

ascitic fluid. Still, an accurate clinical history is helpful in the differential diagnosis.

Figure 26-36 Ovarian carcinoma in ascitic fluid. *A* A large papillary cluster composed of large tumor cells. *B*. Large cancer cells with prominent nucleoli arranged in loose clusters and chains. *C*. A peculiar arrangement of cells in which the central cells are surrounded by a layer of peripheral macrophages. This finding is not unique to ovarian carcinoma. *D*. A cluster of cancer cells of moderate sizes containing a psammoma body (arrow).

Borderline (Low Malignant Potential) Serous Tumors

The uncommon metastatic low-grade (borderline) serous ovarian tumors, discussed at length in Chapter 15, may occasionally have a rather **characteristic cytologic presentation in ascitic fluid**. These tumors may be recognized by **large monolayer sheets or plaques of fairly uniform cells with** irregular, somewhat hyperchromatic nuclei (Fig. 26-38). The findings in **peritoneal lavage fluid**, discussed and illustrated in Chapter 16, and for that matter in effusions, may differ from the above. In many instances, the **cytologic picture is similar to that observed in serous carcinomas, whether primary in the ovary or the peritoneum** (see above). This observation was confirmed by Stewart and Kennedy (1998) who reported that, in peritoneal lavage fluids, the cytologic presentation of these tumors was more in keeping with fully malignant serous carcinoma and included papillary and acinar clusters and single cells with vacuolated cytoplasm and nuclear abnormalities. These authors concluded that the differential diagnosis between borderline and fully malignant serous tumors required histologic correlation.

Pseudomyxoma Peritonei (Adenomucinosi s and Peritoneal Mucinous Carcinomatosis)

Pseudomyxoma peritonei (gelatinous ascites) has been traditionally attributed to **ruptured ovarian mucinous tumors**. As discussed at length in Chapter 15, current evidence strongly suggests that the origin of many, if not most, of pseudomyxomas occur as a complication of a **ruptured mucoid tumor or mucocele of the appendix**. Rarely, pseudomyxoma may occur as a complication of mucinous tumors of **Meckel's diverticulum**. In the latter situations, the disease may occur also in males. Other sources of pseudomyxoma in **gastrointestinal mucinous carcinomas** have also been described (Ronnett et al, 1995). Because of substantial differences in the prognosis of pseudomyxoma peritonei according to the histologic patterns and source of origin, new terminology has been introduced: **disseminated peritoneal adenomucinosis**, comprising lesions with nonmalignant epithelial component, and **peritoneal mucinous carcinomatosis**, caused by obvious carcinomas. A third, **intermediate group**, comprising features of both mucoviscidosis and carcinomatosis, has also been identified (Ronnett et al, 1995, 2001). Still, whether **cytologically benign or malignant**, the cells derived from such tumors, either by spontaneous or incidental rupture of the capsule, have a propensity to **grow on peritoneal surfaces and produce mucus**. Mucus production results in formation of **pseudomyxoma peritonei**, which may lead to enormous abdominal distention.

Figure 26-37 Carcinomas of ovary. *A.* A loosely structured cluster of cancer cells of moderate sizes, corresponding to the pattern of well-differentiated serous adenocarcinoma shown in *B.* *C.* Large cancer cells, some of which have vacuolated cytoplasm and thus resemble signet ring cells, corresponding to moderately well-differentiated papillary serous carcinoma of ovary shown in *D.*

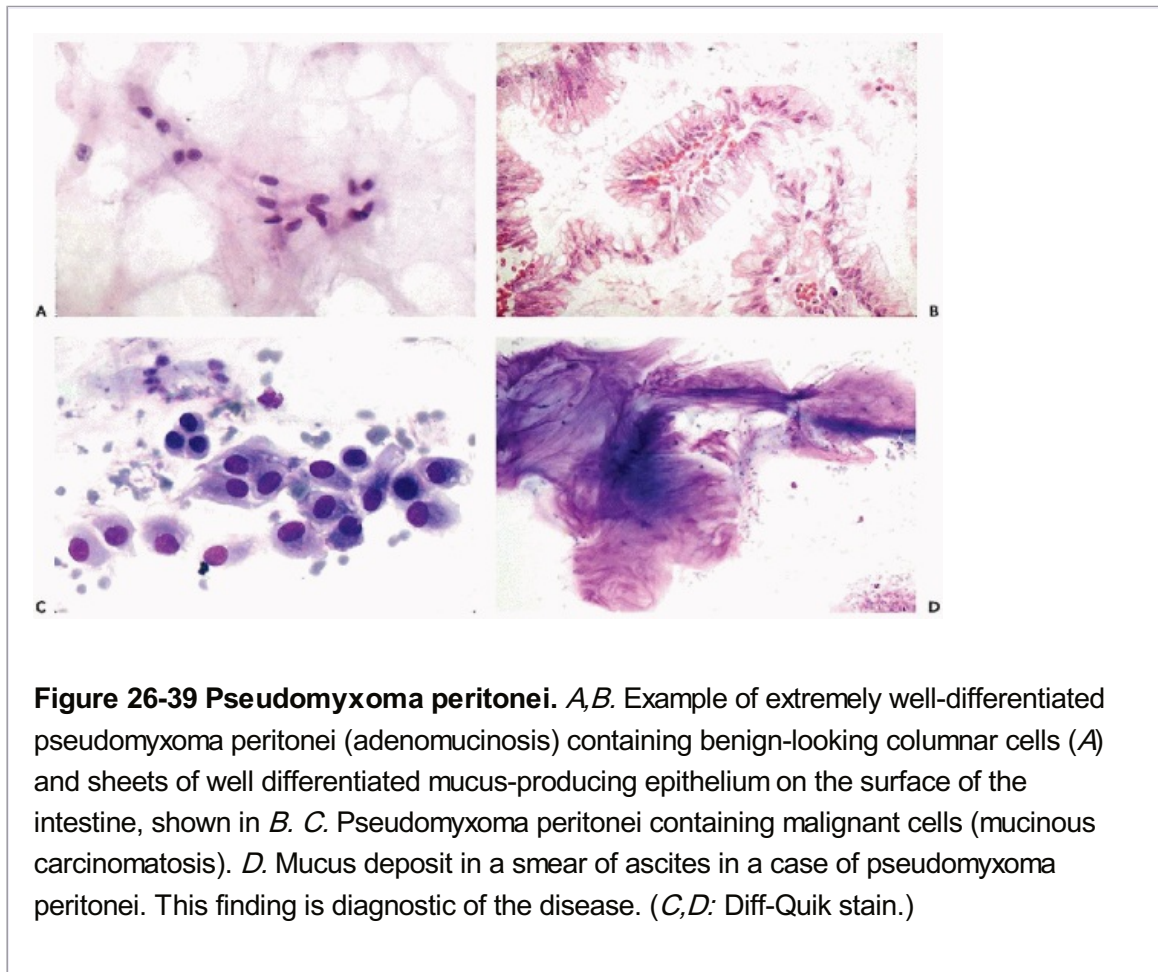

Figure 26-38 Very low-grade (borderline) ovarian cancer (the so-called endosalpingioma) in ascitic fluid (*A*) and in a section from the ovary (*B*). The cytologic presentation in plaques is quite characteristic.

P.987

The gross and cytologic presentation of pseudomyxoma peritonei is quite characteristic. The material obtained from the abdominal cavity is a **viscous, whitish or yellowish fluid**. On microscopic examination, there are very few cells and the customary population of macrophages, mesothelial cells, and leukocytes is absent. **Well-differentiated columnar cells with clear, transparent cytoplasm and small, even nuclei, occurring singly, in small clusters, or sometimes strips of cells arranged in a palisade, floating in thick mucus,**

are characteristic of **peritoneal adenomucinosis** (Fig. 26-39A,B). In mucinous carcinomatosis, obvious cancer cells may be observed (Fig. 26-39C). Occasionally, only **acellular streaks of thick mucus** are observed, recognized by the fibrillar structure and orange-reddish color in Papanicolaou-stained material. In May-Grünwald-Giemsa stain and related stains, the **mucus stains purple or magenta** (Fig. 26-39D). This finding alone is **strongly suggestive of pseudomyxoma peritonei**. Leiman and Goldberg (1992), Mulvany and Ooi (1996), and Gu and Zuna (1997) reported essentially similar observations. Jackson et al (2001) applied the new subdivision of these lesions to cytologic analysis and were able to discern the patterns of of peritoneal adenomucinosis and mucinous carcinomatosis in nearly all of 67 patients.

Recent evidence strongly suggests that the survival of patients with pseudomyxoma peritonei differs according to the histologic and cytologic patterns. Patients with disseminated peritoneal adenomucinosis live longer and may even be cured of the disease but patients with peritoneal mucinous carcinomatosis have a poor treatment outcome (Yan et al, 2001; Ronnett et al, 2001). Still, in my experience, even the benign mucus-producing cells are difficult to eradicate and, sooner or later, most patients usually die of intestinal obstruction.

Endometrioid Carcinoma

Metastatic endometrioid carcinoma, whether of **endometrial or ovarian origin**, may produce ascites or pleural effusion.

P.988

The cytologic presentation has **few characteristic features** beyond those of adenocarcinomas, as described above. Psammoma bodies may occasionally be observed. For

cytologic manifestations of endometriosis, see Chapters 16 and 25. A rare case of **malignant pleural endometriosis** was described by Labay and Feiner (1971). Soslow et al (2000) pointed out that even patients with **intraepithelial serous carcinoma** of endometrium may develop peritoneal carcinomatosis because of synchronous foci of extrauterine serous carcinomas.

Other Ovarian Tumors

Occasionally, metastatic ovarian tumors in effusions may produce a mixed population of cancer cells, **combining the features of a serous carcinoma with mucus-producing cancer cells of signet ring type** (see Fig. 26-37C,D). Histologically, such tumors are usually predominantly of the serous type containing foci of mucus-producing cells.

Mesodermal mixed tumors (Müllerian mixed tumors), whether primary in the uterus, ovary, or fallopian tubes, may metastasize widely and cause ascites, and later on pleural effusion. The histologic and cytologic presentation of these tumors is discussed in Chapter 17. In effusions, clearly malignant cells, sometimes **multinucleated and of very large sizes**, may be identified next to cells and cell clusters indicative of adenocarcinoma (Fig. 26-40). As shown in Chapter 17 and in Figure 24-40B, the presence of **rhabdomyoblasts**, elongated cells with a cytoplasm showing cross-striations, is diagnostic of metastatic rhabdomyosarcoma which, in most cases, indicates the presence of a mesodermal mixed tumor with a component of rhabdomyosarcoma.

Figure 26-40 Ovarian mesodermal mixed tumors in ascitic fluid (A-C from the same case). *A.* Cluster of small malignant epithelial cells, suggestive of an adenocarcinoma. *B.* Cluster of poorly differentiated cells with one of them showing cytoplasmic cross striations consistent with rhabdomyosarcoma. The tumor of origin is shown in *C.* *D.* Air-dried DiffQuik-stained, very large tumor cells from a case of metastatic uterine mesodermal mixed tumor.

Dysgerminomas of ovary can produce metastases and ascites. Cells of **dysgerminoma** are **usually single or form small clusters**. The large nuclei are usually provided with large nucleoli. **Lymphocytes and multinucleated giant cells** may occur. **Metastatic seminomas**

of testicular or of mediastinal origin have a cytologic presentation identical with ovarian dysgerminoma. It is of interest that metastases of dysgerminoma do not necessarily indicate a hopeless prognosis and, with vigorous treatment, recovery is possible.

Stastny et al (1996) described an **ovarian adenocarcinoma with rhabdoid features** in an adult woman. The tumor metastasized to the peritoneal fluid and the cancer

P.989

cells were large, with eccentric clear nuclei, prominent nucleoli, and **inclusion-like condensations of the cytoplasm**, sometimes indenting the nucleus. Electron microscopy documented that the "inclusions" consisted of bundles of intermediate filaments. No features of muscle cells were observed. It is of note that similar **cytoplasmic inclusions, composed of bundles of cytoplasmic filaments** encroaching on the nucleus, may be observed in **Merkle cell tumors** (see Chap. 34).

In young girls and women, **embryonal carcinomas of the ovary** may occasionally be observed. For cytologic presentation of this tumor in cervicovaginal material, see Chapter 15. For further comments on cytologic presentation of this tumor in effusions **in children**, see below.

An **ovarian yolk-sac tumor** was identified in ascitic fluid by Roncalli et al (1988). In the cell block of the sediment, the characteristic periodic acid-Schiff (PAS)-positive **hyaline globules** also stained with an antiserum to **alpha-fetoprotein**.

Occasionally, **primary squamous carcinomas originating in benign teratomas** (dermoid cysts) of the ovary may form metastases leading to peritoneal effusion. Their presentation is identical to other squamous cancers, discussed above.

Other Tumors of the Female Genital Tract

Metastatic tumors of the **uterine cervix** are uncommon in effusions. The cancer cells reflect tumor type (squamous or adenocarcinoma) and have no specific features that would allow organ identification. Two cases of **metastatic small cell carcinoma of the uterine cervix** with dispersed, small cancer cells in effusions were described by Khunamornpong et al (2001). For comments on the presence of **human papillomavirus DNA** in metastatic tumors from the cervix, see Chapter 11.

Metastatic endometrioid carcinomas, whether of endometrial or ovarian origin, were discussed above. Occasionally, however, they have the **pattern of a poorly differentiated tumor**. **Psammoma bodies** may occur in these tumors.

Carcinomas of the Gastrointestinal Tract

The pathology of these tumors is discussed in Chapter 24.

Carcinomas of the esophagus are, for the most part, **squamous carcinomas** and their presentation in effusions is identical to metastatic squamous cancer of other organs, discussed above (see Fig. 26-32). **Esophageal adenocarcinomas** in effusions cannot be distinguished cytologically from metastatic gastric cancer.

Most tumors of **gastric or colonic origin** are **mucus-producing adenocarcinomas**, most commonly observed in ascitic fluid but also in pleural and even pericardial effusions. The cytologic presentation depends on tumor type: **well-differentiated carcinomas differ from signet-ring cell carcinoma and other poorly differentiated carcinomas**.

Signet-ring cell carcinomas present as **single cancer cells**, i.e., large, approximately **spherical cells** with a **peripheral, large hyperchromatic nucleus** and a single, large **cytoplasmic vacuole** (Fig. 26-41A,B). The presence of mucin in such cells may be documented by mucicarmine stain. The signet ring cancer cells must be differentiated from **vacuolated macrophages**, which may have a similar general configuration but are much smaller and **lack nuclear abnormalities**. Occasionally, **lobular carcinoma of the breast** may form cells similar to the gastrointestinal signet-ring cells, but the **mammary malignant cells are much smaller** (see above and Fig. 26-28D).

Poorly differentiated adenocarcinomas shed cancer cells that lack obvious mucin production, are often approximately **spherical**, have an opaque cytoplasm, granular, centrally located **large nuclei** with a moderate level of hyperchromasia, and **large nucleoli**. Occasionally, gastric cancer cells form **spherical (papillary) clusters** that cannot be differentiated from other adenocarcinomas (see Fig. 26-4).

Well-differentiated gastrointestinal adenocarcinomas, particularly of the colon, may be recognized by the presence of **columnar cancer cells** with **large, hyperchromatic nuclei**. Koizumi and Schron (1997) pointed out that, in some metastatic colonic cancers, the **nuclei of cancer cells are pale and transparent**, although still provided with large nucleoli (Fig. 26-41C,D).

Pozalaky et al (1983) reported that **cancer cells of colorectal origin in effusions have a characteristic electron microscopic feature that facilitates their recognition**. The presence of microvilli, with **dense cores of microfilaments** that extend deeply into the cytoplasm ("**cytoplasmic root-lets**"), was only observed in cells of colorectal origin (Fig. 26-42) but not in cells of pulmonary and ovarian adenocarcinomas.

Yonemura et al (2001) reported that a polymerase chain reaction (PCR) assay for **matrix metalloproteinase** in lavage of patients with gastric carcinoma may be a good indicator of micrometastases. The positive assay complemented routine cytology on the same samples as a predictor of prognosis.

Pancreatic and Hepatocellular Carcinomas

The pathology of these tumors is discussed in Chapters 38 and 39.

Pancreatic duct carcinomas have no distinguishing features in fluids. The large cancer cells, easily recognizable as malignant, usually have large nucleoli and, occasionally, a make-up suggestive of adenocarcinoma. Centeno et al (1996) reported cytologic findings in **peritoneal washings** in eight **pancreatic mucinous cystadenocarcinomas**. In four of the tumors, malignant cells were observed. Well-differentiated tumors shed papillary clusters of cancer cells, whereas poorly differentiated tumors shed cancer cells without distinctive features. Centeno emphasized **limited value of peritoneal washings in the prognosis** of these tumors because three of the four patients with negative cytology had unresectable tumors.

Figure 26-41 Carcinoma of large bowel. *A,B.* Pleural fluid showing typical signet ring cancer cells with the large nucleus pushed to the periphery by a deposit of mucus. *C.* Carcinoma of cecum in ascitic fluid. The typical columnar cancer cells may be observed. These cells showed minor nuclear abnormalities. *D.* Biopsy of a metastasis from the same primary tumor in the liver.

Hepatocellular carcinoma cells may be observed in ascitic fluids and sometimes in pleural effusions. Several such cases have been observed personally and by others (Falconieri et al, 1995; Rosendale and Dusenbery, 1996). In well-differentiated tumors, the cancer cells resemble hepatocytes. They are usually of moderate size, but occasionally large, either occurring singly or in small clusters, wherein the cells were occasionally **polygonal**. The **cytoplasm** was granular, occasionally **bile stained**, but no bile canaliculi could be identified under the high power of the light microscope. The moderately hyperchromatic nuclei were **large, spherical, sometimes double**, and contained nucleoli of moderate size. **Specific cytoplasmic features** of such cells, such as **bile-like material and formation of bile canaliculi**, were identified by ultrastructural studies (Woyke et al, 1974).

Carcinomas of the Thyroid

The pathology of these tumors is discussed in Chapter 30. **Papillary thyroid carcinomas** and their **follicular variant** in effusions usually form small, **compact, approximately spherical (papillary) clusters of small cells** that, at the first look, may look inconspicuous. There are **two features** that are helpful in their identification: the small **nuclei** show **folds or creases** and **intranuclear cytoplasmic inclusions ("nuclear holes")**. Also, the cluster often contains **psammoma bodies** (Fig. 26-43). Although other cancers may form psammoma bodies, as discussed above, or intranuclear cytoplasmic inclusions (for example, malignant melanomas, see below), **the combination of small clusters of cancer cells with both features is diagnostic of metastatic papillary carcinoma of the thyroid**. There is no information on the presentation of other types of thyroid cancer in effusions.

Renal Carcinomas

For pathology of these tumors, see Chapter 40. **Metastatic renal carcinomas** of the common

clear or granular cell type in effusions are usually represented by cancer cells of moderate sizes with **abundant, finely vacuolated, faintly eosinophilic, transparent cytoplasm and spherical, bland, or hyperchromatic nuclei with prominent nucleoli** (Fig. 26-44A,B). The cancer cells in effusions are similar to those in the urinary sediment (see Chap. 23). If a cell block is available, positive staining of tumor cells for **keratin and vimentin** confirms the renal origin (Fig. 26-44C,D). Except for their larger size and nuclear features, the cells have some similarity to macrophages. Their identity can be confirmed by keratin stain (Fig. 26-45). In a few patients with malignant effusions with unknown primary site, **renal cancer primary was suggested based on cytologic findings.**

P.991

Figure 26-42 Electron micrograph of a cluster of metastatic cancer cells of rectal origin in pleural fluid. Note the numerous microvilli on cell surface with deep “cytoplasmic rootlets” (RTS). *Inset:* The dense filamentous core of the microvilli and the rootlets extending deeply into the cytoplasm are shown. (d, desmosomes; GB, glycocalyceal bodies; RTS, rootlets; T, tight junction.) ($\times 9,000$; *inset* $\times 36,000$.) (From Pozalaky Z, et al. Electron microscopic identification of the colorectal origins of tumor cells in pleural fluid. *Acta Cytol* 27:45-48, 1983.)

We have not observed the very rare metastatic **papillary or sarcomatoid renal carcinomas in effusions**, but a few such cases were reported in a retrospective study by Renshaw et al (1998). In Renshaw's experience, the cells of papillary carcinomas formed papillary clusters whereas the sarcomatoid carcinomas shed spindly cancer cells. It is debatable whether these relatively rare variants of renal cancer can be recognized in fluids, as of renal origin, in the absence of clinical history.

Urothelial Carcinomas

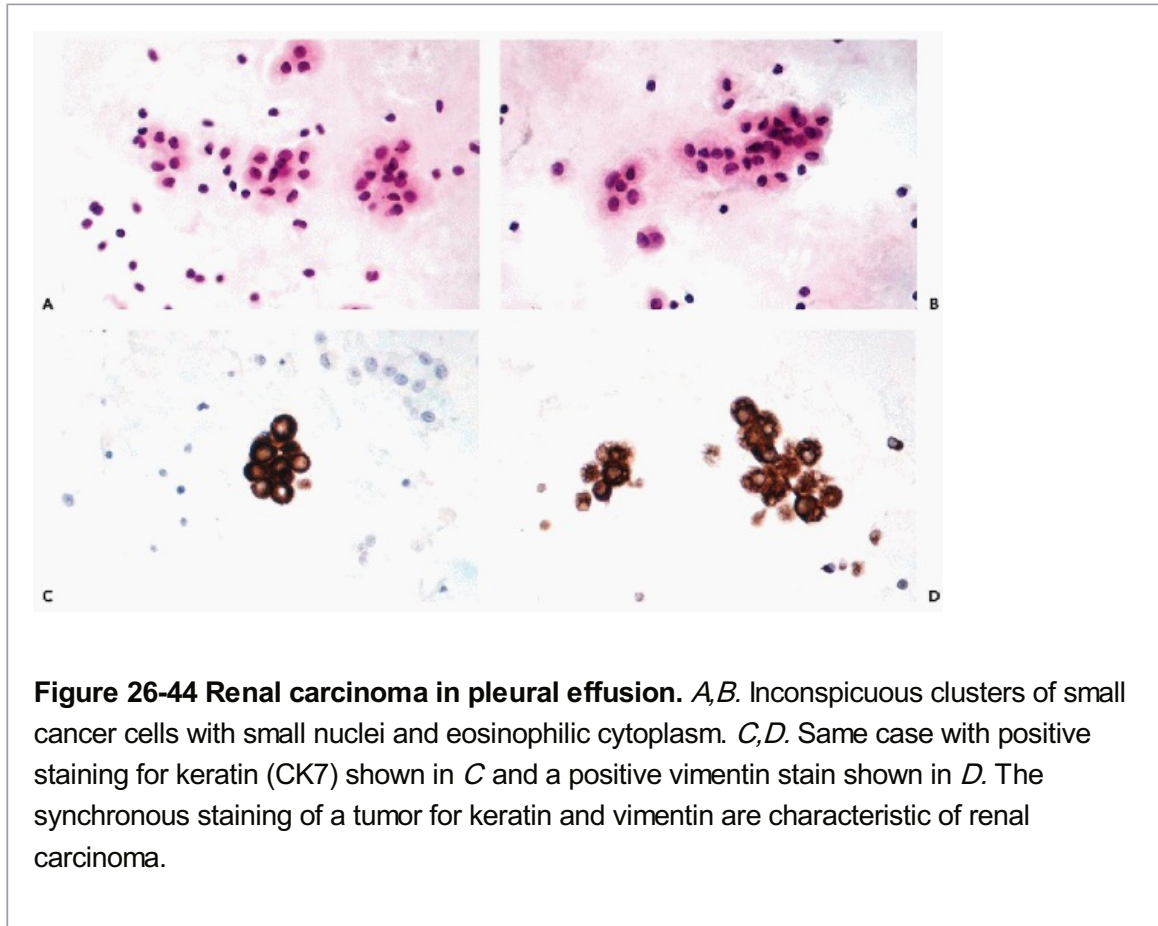

Although metastatic urothelial cancer may display recognizable features in aspiration of biopsies of lung, as discussed in Chapter 20, so far we have not observed them in effusions. In most cases, the fluids contain **undifferentiated, large cancer cells**, sometimes with a **sharply outlined cytoplasm**, suggestive of squamous derivation. Sometimes the cells are elongated but do not resemble the "cercariform cells" described and discussed in Chapter 23 (Powers and Eldair, 1995; Renshaw and Madge, 1997; Hida and Gupta, 1999). Occasionally, the cells are multinucleated, vaguely **resembling the umbrella cells**, described in Chapter 22, and sometimes observed in metastases (see Chap. 20). In a case of metastatic urothelial carcinoma of renal pelvic origin, we observed **psammoma bodies**. There is no published experience with the use of **uroplakin antibodies** in effusions (Moll et al, 1995; Wu et al, 1998; Li et al, 1999). **Metastatic adenocarcinomas and squamous cancers** of the bladder and renal pelvis usually show the features diagnostic of this tumor type but are otherwise not specific.

Other Types of Cancer of the Genitourinary Tract

Metastatic prostatic carcinomas appear as typical **adenocarcinomas**, composed of cells of various sizes, depending on the configuration of the primary tumor. In some patients, the origin of these cells may be identified by immunocytologic staining for **prostate specific antigen or prostatic acid phosphatase** (see Chap. 33). Renshaw et al (1996) pointed out that **only one half of the 10 patients**

P.993

studied displayed positive immunostaining and, therefore, the absence of immunoreactivity does not rule out prostatic origin of cancer cells.

Endocrine Tumors

Metastatic Carcinoids

The histologic and cytologic features of carcinoids are discussed at length in Chapters 20, 24, and 38. Very rarely, effusion may contain a population of **monotonous small spherical or somewhat elongated cancer cells**, with eosinophilic cytoplasm and small, **eccentric nuclei** of a **finely granular, “salt and pepper”** configuration, containing very small but visible nucleoli. The cells, which form small clusters, measure about 12 to 15 μm in diameter and sometimes more and are, therefore, somewhat larger than plasma cells which they resemble. In the presence of such effusions, the possibility of a metastatic carcinoid tumor should be considered. The differential diagnosis includes other small cell tumors, including plasma cell myelomas and malignant lymphomas, discussed below. In all cases, tissue evidence is necessary to confirm the diagnosis.

Other Endocrine Tumors

It is most unusual to recognize in effusions a tumor with endocrine features, other than carcinoid. Most of such tumors have the features of a poorly differentiated carcinoma. Their **endocrine features can be recognized only by immunocytochemistry.**

MALIGNANT DISORDERS OF LYMPHOID AND HEMATOGENOUS ORIGIN

Malignant Lymphomas

The cytologic diagnosis of a malignant lymphoma in an effusion can be established in most cases on morphologic evidence. Such a diagnosis is often of significant therapeutic and prognostic value. A rapid identification of the disease may lead to aggressive treatment and may be compatible with many years of useful life.

The picture of malignant lymphoma became more complicated with the onset of AIDS. As early as 1990, Wals et al noted that patients with AIDS are prone, not only to malignant lymphomas, but also to **other lymphoproliferative disorders**. Of special interest is malignant lymphoma of the primary body cavities, briefly discussed in the first part of this chapter. A sophisticated analysis of cells in effusions, including **immunologic profiles of cells** by immunocytology, flow cytometry, and **cytogenetic documentation**

P.994

of gene rearrangement, may be required to reach the correct diagnosis, as discussed in Chapter 31.

Figure 26-45 Renal carcinoma in pleural fluid. *A.* Large vacuolated cells with large hyperchromatic nuclei, mimicking large macrophages. *B.* CAM 5.2 keratin stain of the same cells documenting their epithelial nature. *C.* Another example of metastatic renal carcinoma composed of large cells with vacuolated cytoplasm, corresponding to the tissue section shown in *D.*

Within recent years, the histologic terminology of various types of malignant lymphoma has been repeatedly modified, and the current classification is discussed in Chapter 31.

However, **for the purposes of cytologic recognition in effusions, the malignant**

lymphomas can be divided into four groups:

- **Large-cell lymphomas**
- **Small-cell lymphomas**
- **Hodgkin lymphoma**
- **Miscellaneous lymphoproliferative and hematologic disorders, including rare types of lymphomas, plasma cell myelomas, and leukemias**

A summary of distribution of malignant lymphomas in effusions from the classical study by Melamed (1963) is shown in Table 26-3.

Regardless of the type of malignant lymphoma, the cancer cells from such cases **almost never form cohesive, organized aggregates of cells**. Although **superposition of these cells into thick clusters** may occur, it is usually an **artifact** of preparatory techniques. Cells of malignant lymphomas do not form associations with each other and the **cancer cells lie singly**. It is permissible to state that, in effusions, a malignant tumor characterized by organized cell clusters is **not** a malignant lymphoma, regardless of the size and make-up of individual cells, although rare exceptions may occur (see Fig. 26-47C). **The diagnosis of malignant lymphoma is made as much on the pattern of smears as on individual cell abnormalities**. The latter are described in some detail according to predominant tumor type.

Large-Cell Lymphomas

This group comprises **B- and T-cell lymphomas, with or without cleaved nuclei**, including the immunoblastic and lymphoblastic types and some uncommon lymphomas, such as the Ki-1 lymphoma and primary lymphoma of body cavities in AIDS patients that were recognized within the recent years.

Cytology

Malignant lymphomas of large-cell type are the **easiest to diagnose cytologically**, because the cell abnormalities are usually well evident. The smear usually shows a dispersed **population of large malignant cells with relatively scanty cytoplasm** (Fig. 26-46A). Some variability of cell sizes may

P.995

occur among cases. Most cells are approximately spherical, but there is usually some **variation in cell shapes**. Rarely, bizarre cells may occur.

TABLE 26-3 INCIDENCE OF MALIGNANT CELLS IN EFFUSION ACCORDING TO HISTOLOGIC TYPE OF MALIGNANT LYMPHOMA

Histological Diagnoses	Cytologic Evidence of Cancer				
	Total	Present		Susp.,	Not Pres.,
	No. Pt.	No. Pt.	% Pt.	No. Pt.	No. Pt.
Large-cell lymphoma	71	53	75	7	11

Lymphocytic lymphoma					
Diffuse	32	19	59	6	7
Nodular	16	9	56	3	4
Hodgkin's disease	56	14	25	6	36
Acute leukemia	10	5		3	2
Chronic leukemia	6	4		1	1
Leukolymphosarcoma	4	4			
Plasmacytic myeloma	3	2		1	
Letterer-Siwe disease	2	1		1	

No. Pt., number of patients. (Terminology modified from Melamed MR. The cytological presentation of malignant lymphomas and related diseases in effusions. Cancer 16:413-431, 1963.)

The **scanty cytoplasm of the cancer cells** is transparent and may be either basophilic or eosinophilic (Fig. 26-46B). The **nuclei** of these cells may be **spherical or oval**, but often have an **irregular contour**. Nuclear **indentations or cleavage** and single or multiple **nuclear protrusions** in the form of **small, tongue- or nipple-like projections**, are characteristic of malignant lymphoma cells and are uncommon in other malignant tumors (Fig. 26-46C). Atkin and Baker (1964) observed **nuclear protrusions** in an ovarian carcinoma in ascitic fluid and attributed the protrusion to an abnormally **long marker chromosome**. Similar observations have been reported on cancer cells in cervical smears, discussed in Chapter 11. It is of interest that an early analysis of chromosomal make-up of malignant lymphomas by Miles et al (1966) yielded several tumors with long marker chromosomes. Whether the nuclear protrusions, so often observed in cells of large-cell lymphoma in effusions, are always caused by long marker chromosomes remains to be determined. For further comments on cytogenetics of malignant lymphomas, see Chapter 4.

Nucleolar abnormalities are frequent and often striking in large-cell lymphomas. The nucleoli are **large, irregular in shape, and often multiple** (Fig. 26-46C). We have never observed a large-cell lymphoma without obvious nucleolar abnormalities. Usually, there is some **relationship between the size of the nucleus and the nucleolus**: larger tumor cells have larger (and sometimes more numerous) nucleoli than smaller tumor cells). Prominent chromocenters may also be present.

Mitotic activity is often intense and **abnormal mitotic figures are common** (Fig. 26-47A). Another common feature of large cell malignant lymphomas in effusions is **nuclear fragmentation**, previously referred to as **karyorrhexis**, and now recognized as **apoptosis** (Figs. 26-46A, 26-47B). Although this feature is more common in small cell lymphomas (see

below), it does occur in the large cell variant. We observed apoptosis in previously untreated lymphomas but this phenomenon may be enhanced by treatment.

In a classic case, the diagnosis of large-cell lymphoma in effusions presents comparatively little difficulty, both for the presence of malignant disease and the identification of the tumor type (see Fig. 26-46). **At both ends of the spectrum, diagnostic difficulties may arise.** If, on the one hand, the tumors are composed of fairly uniform cells of medium size, **the differentiation from a small-cell lymphoma may be a matter of individual opinion**, as is also the case with histologic material. The controversy is best solved by immunochemistry or, if necessary, by cytogenetic studies.

On the other hand, **Ki-1 lymphomas may resemble metastatic carcinomas.** This is the prototype of **large-cell lymphomas with abundant cytoplasm.** The large cancer cells **lie singly** but may also form clusters mimicking carcinoma. The cells display the **same nuclear abnormalities as other large cell lymphomas**, but are provided with **ample basophilic, and sometimes eosinophilic cytoplasm** that make the **differentiation from a metastatic carcinoma very difficult** on morphology (Fig. 26-47C). Because this tumor may occur in any age group and has a **surprisingly good prognosis**, its recognition is important to the patient. Most such tumors are initially diagnosed as metastatic carcinomas,

P.996

a diagnosis that cannot be confirmed by clinical findings.

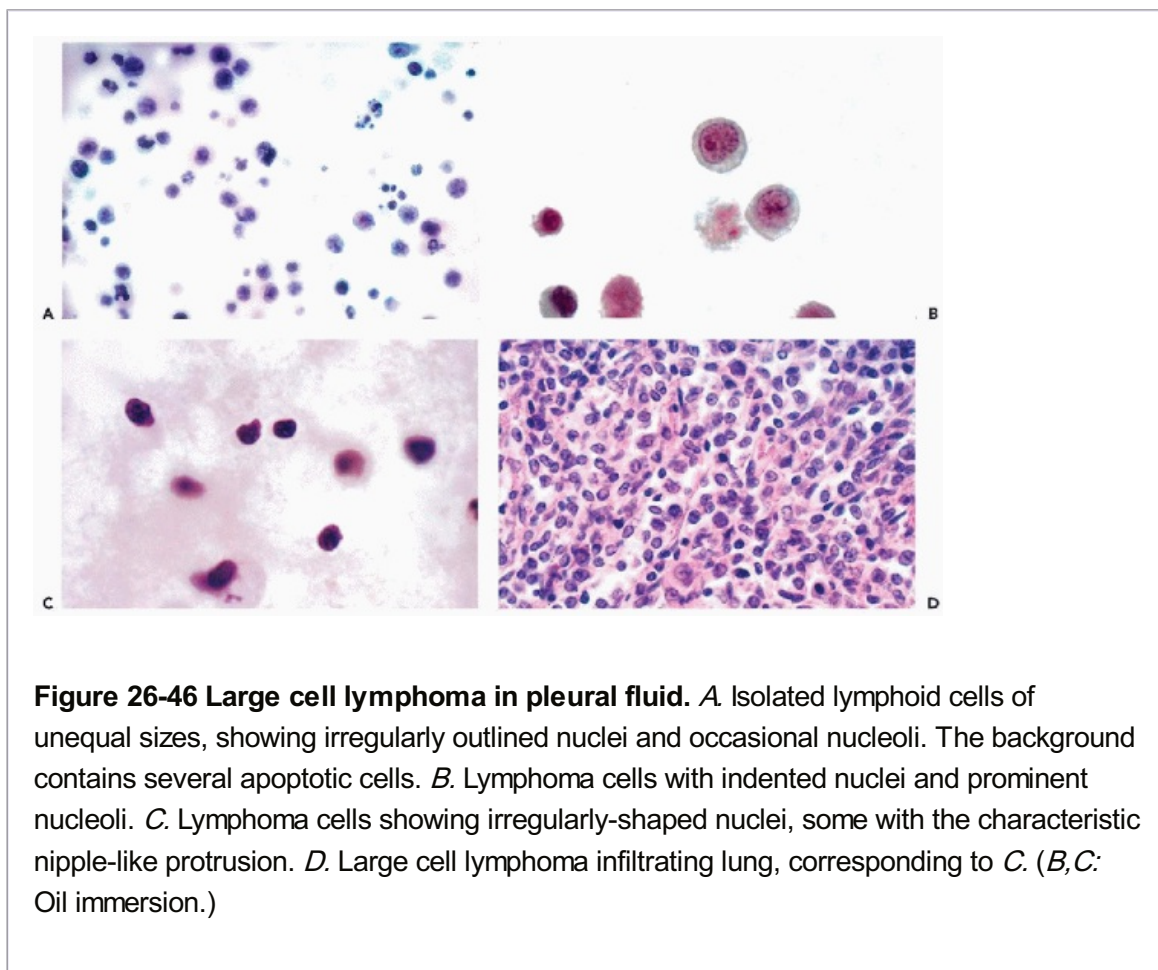

Figure 26-46 Large cell lymphoma in pleural fluid. *A.* Isolated lymphoid cells of unequal sizes, showing irregularly outlined nuclei and occasional nucleoli. The background contains several apoptotic cells. *B.* Lymphoma cells with indented nuclei and prominent nucleoli. *C.* Lymphoma cells showing irregularly-shaped nuclei, some with the characteristic nipple-like protrusion. *D.* Large cell lymphoma infiltrating lung, corresponding to *C.* (*B,C:* Oil immersion.)

Immunochemistry is usually initiated because of a discrepancy between the cytologic diagnosis and the clinical findings. **Reactivity of the cancer cells with lymphocyte common antigen (LCA), the CD30 monoclonal antibody** which stains the cell membrane, and the **anaplastic**

lymphoma kinase (ALK), which stains the nucleus and the cell membrane, confirms the diagnosis of Ki-1 lymphoma (Fig. 26-47D).

The number of published cases of Ki-1 lymphoma with effusions is small. Jiminez-Heffernan et al (1997) observed a case of Ki-1 lymphoma with pleural effusion in a transplant patient. Dunphy et al (1998) described a similar tumor in pleural fluid in a patient with AIDS. Burja et al (1997) reported a case of Ki-1 lymphoma with simultaneous pleural and peritoneal effusions. Another case was published by Das et al (1999).

Burkitt's Lymphoma

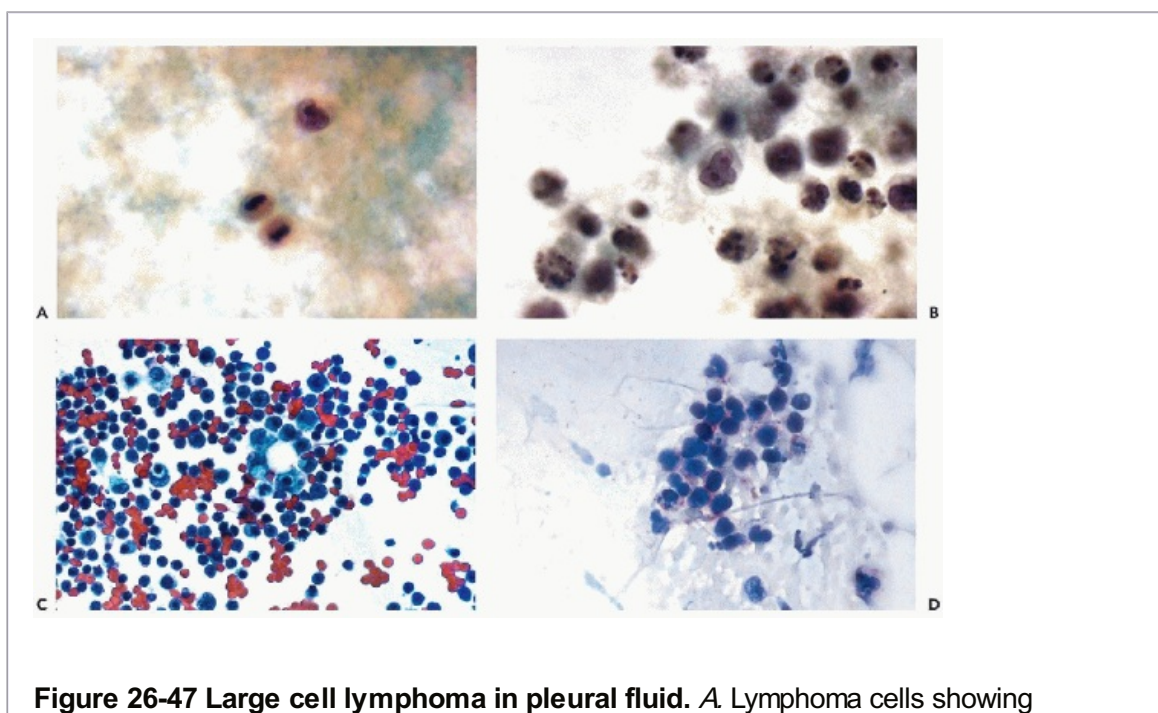

Cells of this variant of lymphoma may occasionally be observed in ascitic fluid. In a personally observed case in a 3-year-old boy, the fluid contained **malignant cells of lymphoid type with small nuclear vacuoles**, accompanied by **large macrophages**, some of which were smudged, presumably during smear preparation (Fig. 26-48). The biopsy of a retroperitoneal lymph node revealed the classical "starry sky" appearance of the tumor. For further information of Burkitt's lymphoma, see Chapter 31.

Small-Cell Lymphoma

For the most part, these are B-cell lymphomas, although T-cell lymphomas may occur. Izban et al (2001) described such a case with ascites as the first symptom. This type of malignant lymphoma is usually characterized in effusions by a large **population of monotonous, small lymphoid cells 6 to 12 μ m in diameter**, sometimes somewhat larger (Fig. 26-49A). The most common diagnostic presentation is "**the variable lymphocytic type**" (Melamed, 1963). The name is based on variation in the size of these cells within the relatively narrow limits. The cells are usually round or oval, with very **scanty, barely visible basophilic cytoplasm**. The nuclei are **moderately hyperchromatic**, occasionally **cleaved or somewhat irregular in shape**, but mainly round or oval (Fig. 26-49B). **Small nucleoli are**

P.997

present in many of the cells, but they do not stand out as in large-cell lymphomas. Small **irregularities of the nuclear contour and nuclear protrusions** may be observed.

mitoses. *B.* Malignant lymphoma cells showing marked apoptosis and irregular nuclei with prominent nucleoli. *C.* Large T-cell lymphoma in pleural fluid showing a very unusual gland-like arrangement of cells, mimicking an epithelial tumor. *D.* Positive lymphocyte common antigen (LCA) in cells shown in *C.* (*B:* oil immersion.)

Another helpful feature in identifying cells of lymphocytic lymphoma (and chronic lymphocytic leukemia) in effusions is the **granularity of the nuclei**. The feature was first described by Spriggs and Vanhegan (1981) as *cellules grumelées* or “lumpy cells,” characterized by numerous **coarse aggregates of chromatin in otherwise spherical nuclei**. Seidel and Garbes (1985) reviewed the diagnostic value of this feature and found it to be a useful fixation artifact that occurred only in malignant disorders, but not in benign lymphocytes.

Nuclear fragmentation in the form of **massive apoptosis (karyorrhexis)** of nuclei may occur and is **diagnostic of this group of diseases** (see Fig. 26-47B). This phenomenon has been repeatedly observed in the absence of any history of treatment but may be enhanced by treatment (see below). **Massive karyorrhexis has not been observed by us in any tumors other than malignant lymphoma, usually but not always of small-cell type.**

The characteristic classical cytologic presentation of small-cell lymphoma is virtually never confused with other cancers, but may be **mistaken for an inflammatory reaction**. A technically impeccable preparation is required for analysis of the morphologic details for diagnosis which cannot be made with the help of various filter devices or other technical shortcuts. The determination of **monoclonality** of the lymphocytes and of the flow cytometric profile is advisable (Fig. 26-49D). As always, clinical history and knowledge of the hematologic and immunologic status of the patient is helpful. Immunologic analysis is needed for further classification of the tumors (Bangerter et al, 2001).

We observed a most **unusual presentation** of small cell lymphoma in a pleural effusion of a young woman in the form of **abnormal megakaryocytes** that displayed bizarre structure with **prominent nucleoli** and evidence of **marked mitotic activity** (Fig. 26-50). Except for the effusion, the patient had no clinical or hematologic abnormalities. Because the cytologic findings suggested a hematologic disorder, a **bone marrow biopsy** was recommended on which the diagnosis of small cell lymphoma was confirmed (Fig. 26-50D).

Hodgkin Lymphoma

Hodgkin lymphoma in effusions always represents metastatic spread. The diagnosis of Hodgkin lymphoma in fluids can be securely made only if **classical Reed-Sternberg cells are identified**. Although **mononucleated cells with large**

P.998

nucleoli (Hodgkin's cells) and the so-called popcorn cells (multinucleated cells with pale nuclei and small nucleoli) may raise the suspicion of the disease, the diagnosis is clinched if cells with **two or more nuclei and very large nucleoli are observed** (Fig. 26-51). In the binucleated cells, the two oval nuclei, separated by a band of cytoplasm, may form **mirror images** of each other (Fig. 26-51A). It is of interest that the **intact Reed-Sternberg cells floating in fluid are quite often multinucleated**, strongly suggesting that the mirror-image nuclear arrangement, commonly seen in tissues, is a cross section of these cells. It is of note that phagocytized small particles may often be observed in the cytoplasm of such cells (Fig. 26-51C). Accompanying the Reed-Sternberg cells are **scarce mononucleated cells of the type described for large-cell lymphoma, and numerous lymphocytes of various**

types. Plasma cells are occasionally observed but **eosinophiles are scarce**.

Of all forms of malignant lymphoma, the diagnosis of Hodgkin lymphoma is by far the most difficult. Differentiation of Reed-Sternberg cells from atypical mesothelial cells, on the one hand, and from similarly configured epithelial cancer cells, on the other, may be the source of substantial difficulty. **Reed-Sternberg-like cells** in pleural effusion, secondary to pulmonary infarction, were reported by Irwin et al (1978), and in lymphocytic lymphoma and leukemia (Schnitzer, 1970; Tsang et al, 1993). Consequently, Olson et al (2000) applied a **panel of antibodies** to the identification of Reed-Sternberg cells and reported positive staining with **CD15 and CD30 and no reaction with common lymphocyte antigen**.

Rare Types of Lymphomas

Young and Crocker (1984) reported a case of **lymphoplasmacytoid lymphoma**. The tumor cells in pleural fluid contained conspicuous intracytoplasmic **immunoglobulin inclusions**. The case was thought to be a variant of vacuolated B-cell lymphoma, described by Kim et al (1978) and by Harris et al (1981). The cells shown were somewhat similar to the cells of metastatic lobular carcinoma (see Fig. 26-28), except for the absence of the cytoplasmic mucinous inclusions or cell clustering.

Miller et al (1987) described a case of **multilobated lymphoma** in pleural fluid. The highly malignant tumor was characterized by **tumor cells with multilobate nuclei, each lobe provided with a nucleolus**. The tumor was shown to be a B-cell lymphoma, although in its original description by Pincus et al (1979), the neoplasm was thought to be of T-cell derivation. We observed an identical case in cerebrospinal fluid (see Chap. 27).

Figure 26-49 Small cell lymphoma in pleural and ascitic fluids. *A.* A rich population of small lymphocytic cells showing relatively minor nuclear abnormalities. This pattern may be encountered in low grade lymphoma or in chronic lymphocytic leukemia. *B.* Malignant lymphoma cells in pleural fluid showing cleaved nuclei. *C.* Malignant lymphoma cells showing coarse granularity of chromatin (lumpy cells or cellules grumelées). *D.* Immunocytochemical monoclonal kappa stain in a low grade lymphoma.

Vernon and Rosenthal (1979) described the presence of **Sézary cells in ascitic fluid** in a patient with **disseminated mycosis fungoides**, a cutaneous form of T-cell lymphoma. The large malignant cells are characterized by complex nuclear convolutions (“serpentine or cerebriform nuclei”) and scanty cytoplasm (see also Chaps. 31 and 34).

Moriki et al (2000) reported a case of **subcutaneous panniculitic T-cell lymphoma** with pleural effusion. The cytologic findings included **marked phagocytic activity of very large macrophages, showing lymphophagocytosis and erythrophagocytosis, accompanying typical cells of a large cell lymphoma.**

Primary Lymphomas of Body Cavities in AIDS

These uncommon lymphomas have a characteristic clinical presentation: the patient, usually a young person with AIDS, develops a pleural and sometimes peritoneal effusion that on culture fails to yield any known pathogenic organisms (Green et al, 1995; Jones et al, 1996; Ansari et al, 1996; Hsi et al, 1998; Vadmal et al, 1998; Vince, 2001). The fluid recurs after drainage and a sample is finally submitted for a cytologic examination which shows **large malignant cells occurring singly and with a moderate amount of basophilic cytoplasm** (Fig. 26-52A,B). As is the case with the Ki-1 malignant lymphoma, **the differential diagnosis** is with a **metastatic carcinoma** which may also occur in young patients with AIDS. Dunphy et al (1998) also pointed out the morphologic similarity between the primary lymphoma of body cavities and the K-1 lymphoma. The correct diagnosis is usually established by immunologic study of tumors cells which do not express the B- or T-cell antigen (**null cells**), show immunoglobulin gene rearrangement. If necessary, the diagnosis can be confirmed by a molecular search for **Kaposi's sarcoma-associated herpesvirus 8 and EBV**, which are commonly found in these lesions (Knowles et al, 1989; Chang et al, 1994; Cesarman et al, 1995; Mansour et al, 1998).

Wakely et al (2002) used **reverse transcriptase in situ polymerase chain reaction** to document the presence of herpesvirus 8 in cells of primary effusion lymphoma cells with excellent results.

Primary Cardiac Lymphomas

The extremely rare spontaneous primary cardiac lymphomas cause **pericardial effusions** that may lead to a **tamponade**.

P.1000

Accordingly, the primary diagnosis is usually established by cytology of pericardial fluid. First such cases were reported by Pozniak et al (1986) and Castelli et al (1989) and a small number of cases were more recently published (Curtsinger, 1989; Chao et al, 1995).

Figure 26-50 Malignant lymphoma with first manifestation of atypical megakaryocytes, showing mitotic activity in pleural fluid as the first evidence of disease (A-C). D. Bone marrow from the same patient showing well-differentiated malignant lymphoma.

Primary lymphomas also may develop in the **immunosuppressed heart transplant patients**. We observed a case of a **large-cell lymphoma**, first diagnosed by cytology of pericardial fluid and subsequently confirmed by biopsies of the bone marrow and the myocardium in a 52-year-old man with a heart transplant (Fig. 26-52C,D). The patient was effectively treated and was free of disease 3 years later. Thus, the prognosis of cardiac lymphoma is not necessarily hopeless. Jones et al (1998) reported a similar case with the added complication of Kaposi's sarcoma.

Effusions in Leukemias

It is exceedingly rare for patients with leukemia to develop effusions in the absence of prior clinical diagnosis. Hence, the cytopathologist will rarely have the opportunity to establish the primary diagnosis of the disease in effusions. Rather, he will be requested to help delineate the extent of the disease for purposes of treatment, as is also the case with cerebrospinal fluid (see Chap. 27).

Chronic lymphocytic leukemia in effusions gives a fairly uniform cytologic pattern of lymphocytes; its **differentiation** from a **disseminated well-differentiated small-cell lymphoma** is very difficult. The nuclei of lymphoma are more likely to display the pattern of “**lumpy cells**,” described above, than leukemic cells. So far, we have not observed “**hand mirror cells**” in effusions. This variant of lymphocytes, common in leukemias and some lymphomas, is characterized by cells with **cytoplasmic extensions, mimicking the handle of a hand mirror**. The entity is discussed in Chapter 27, in reference to leukemia in the cerebrospinal fluid.

Other leukemic cells may often be identified in effusions. **Acute myeloid and monocytic leukemias may be confused with large-cell lymphoma**. Effusions in **chronic myelogenous leukemia must be differentiated from inflammatory reactions and extramedullary hematopoiesis**. Yam (1985) described an unusual case of **granulocytic sarcoma** (tumor manifestation of chronic granulocytic leukemia) in pleural fluid. The cells were identified as granulocytic precursors by a battery of cytochemical studies. To our knowledge, there are no published cases of **megakaryocytic leukemia** in effusions. The case of small-cell lymphoma with abnormal megakaryocytes in an effusion was described above (see Fig. 26-50).

P.1001

Figure 26-51 Hodgkin lymphoma in pleural fluid. A. Typical Reed-Sternberg cell with two nuclei facing each other. B. Lymph node biopsy corresponding to A. C. Multinucleated Reed-Sternberg cell. D. Section of spleen obtained at autopsy showing Hodgkin lymphoma and corresponding to C. (A, C: Oil immersion.)

It should be noted that patients with various forms of **leukemias, successfully controlled for a period of years, may develop malignant lymphomas** and that this transformation may be observed in effusions (Fig. 26-53A,B).

Plasma Cell Myeloma

Disseminated plasma cell myeloma (**multiple myeloma**) may be occasionally associated with

pleural effusion or ascites. Although Geisinger et al (1986) noted that cytologic manifestations of multiple myeloma occur relatively rarely, in several personal cases, the disease could be diagnosed in fluids, because of **uniform population of easily recognized plasma cells** was observed in smears (Fig. 26-54A-C). In two personally observed cases, **the primary diagnosis of plasma cell myeloma was made in effusions before any clinical evidence of skeletal disease**. In both cases, one of pleural and the other of ascitic fluid, a **pure population of well-differentiated plasma cells** was observed (Fig. 26-54D). In one of the cases, a pleural biopsy disclosed an infiltration with plasma cells and immunoelectrophoresis of the pleural fluid disclosed an abnormal globulin pattern. In **both cases, subsequent evidence of inconspicuous skeletal lesions was obtained, followed by fatal outcome of the disease**.

Again, it must be stressed that **rare plasma cells** may be observed in lymphomas, especially in Hodgkin's disease and in chronic inflammatory processes.

Other Lymphoproliferative Disorders

Severe chronic active Epstein-Barr virus infection may cause lymphoproliferative disorders that may result in lymphoma-like syndrome associated with hemophagocytosis (Ohshima et al, 1998). We have not seen this disorder in effusions.

Waldenstrom macroglobulinemia may, very rarely, present as a pleural effusion. In the case reported by Mansoor et al (2000), the fluid contained clusters of lymphoplasmacytoid cells and small lymphocytes. The diagnosis was established by flow cytometry and detection of B-cell immunoglobulin gene rearrangement.

Differentiation of Malignant Lymphomas and Leukemias From Nonmalignant Disorders

The differentiation of malignant lymphomas from other malignant tumors has been discussed above. However, **small cell lymphomas and chronic lymphocytic leukemia** can present problems in differential diagnosis in **benign**

P.1002

effusions rich in lymphocytes that may occur in a variety of inflammatory processes, mainly tuberculosis. The latter may be accompanied by a very marked proliferation of mesothelial cells that is rarely conspicuous in malignant lymphomas. Lymphocytosis may also occur in effusions associated with **disseminated lupus erythematosus** (see Chap. 25). Another example, quoted by Melamed (1963), was ascitic fluid from a child with **giant cell hepatitis and extensive extramedullary hematopoiesis**.

Figure 26-52 Rare forms of malignant lymphoma. *A,B.* Cells from a malignant lymphoma in pleural fluid from a patient with AIDS. There were no visible tumor masses in this case. *C,D.* High magnification of pericardial fluid from a patient with a heart transplant showing large cell lymphoma (*C*) confirmed by bone marrow biopsy (*D*).

Figure 26-53 Pleural fluid in chronic myelogenous leukemia. *A.* Fifteen years before the development of a high grade malignant lymphoma, shown in *B* (high magnification).

Leukemoid reactions of various types, particularly in patients with AIDS, may also mimic malignant lymphoma or leukemia in effusions.

Most problems of differential diagnosis can be solved by **close attention to the nuclear changes** that occur in small

P.1003

cell lymphomas and chronic lymphocytic leukemias, described in detail above. However, in debatable cases, the cytologic diagnosis of malignant lymphoma or leukemia should be supported by clinical, hematologic, immunologic, and molecular evidence.

Figure 26-54 Multiple myeloma with first manifestation in effusions. *A,B.* High magnification of pleural fluid showing large and somewhat atypical plasma cells, corresponding to the bone marrow biopsy shown in *C*. This relatively young patient subsequently developed the customary osseous manifestations of multiple myeloma. *D.* Another example of multiple myeloma in ascitic fluid. This patient also developed clinical manifestations of multiple myeloma (*B,D:* Giemsa stain.) (*D:* courtesy of Ms. Carol Bales, formerly of Montefiore Hospital.)

MALIGNANT MELANOMAS AND RELATED TUMORS

Metastatic malignant melanomas, of **cutaneous or ocular origin**, may be associated with effusions. Contrary to most other malignant tumors where clinical evidence of metastatic disease usually precedes the accumulation of fluid, **effusions in malignant melanoma may occur as the primary evidence of metastases, sometimes many years after the treatment of the primary tumor**. Thus, the identification of this tumor type may be of considerable diagnostic importance. In fact, this **diagnosis should always be considered in effusions with a population of malignant cells of carcinomatous or unusual configuration in the absence of a known primary tumor**. The presence of **melanin pigment in tumor cells** is characteristic of malignant melanoma (Fig. 26-55A).

Cells of metastatic malignant melanomas in fluids may assume **many forms, ranging from clearly malignant cells of epithelial-type cells of various sizes to spindly cells, mimicking spindle cell sarcomas**. Rarely, **signet-ring-like cells** can be observed, particularly in the rare so-called balloon cell melanoma and in malignant melanotic schwannoma (see below). Most cancer cells **occur singly**, but small cell clusters are common. **Phagocytic cell images (cell-in-cell)** are also frequent. The cells, which are either mono-, bi-, or multinucleated, are often characterized by a **peripheral location of the large, usually coarsely granular nuclei** that often contain **very large single or multiple nucleoli**, which sometimes may occupy a substantial portion of the nucleus (Fig. 26-55B).

Yamada et al (1972) and, subsequently, Hajdu and Savino (1973), pointed out that the presence of large **intranuclear clear zones or “holes” (nuclear cytoplasmic inclusions)** is a frequent event in cells of metastatic malignant melanoma in effusions (Fig. 26-55C). The

nuclear inclusions represent **intranuclear cytoplasmic invaginations** that may be differentiated from very large nucleoli by careful focusing up and down under the high-power lens of the microscope. The **inclusions have an irregular contour, vary in size, depending on the depth of focus, and are present at all levels of the**

P.1004

nucleus. The nucleoli, on the other hand, occupy only a single band of nuclear thickness and are out of focus as soon as the lens is focused above or below them. Smaller nuclear cytoplasmic inclusions may occur **in benign cells** (for example in bronchial cells, see Chap. 19) and in **other malignant tumors**, such as carcinomas of the thyroid and bronchogenic adenocarcinomas, among others.

Figure 26-55 Malignant melanoma in pleural fluid. *A.* Isolated cancer cell with accumulation of finely granular brown pigment in the cytoplasm. *B, C.* High magnification showing a large tumor cell with a prominent nucleolus (*B*) and one with a large intranuclear cytoplasmic inclusion (*C*). *D.* Lymph node biopsy corresponding to *B* and *C*.

Melanotic schwannoma is a rare tumor involving spinal nerve roots and sympathetic ganglia. In histologic sections, the tumor is composed of **epithelioid and spindle cells**, is rich in **melanin**, often contains **psammoma bodies**, and has many similarities with a malignant melanoma. The tumor has been previously identified in aspiration biopsies (FNA) by Sola-Peres et al (1994) and Marco et al (1998).

Jaffer and Woodruff (2000) described a case of this rare tumor in a 44-year-old man with pleural effusion. The fluid contained large tumor cells with abundant cytoplasm. Of note were large, **signet ring-like cells** with single or double hyperchromatic nuclei. Pigmented cells were also present (Fig. 26-56A-C). A direct aspirate of the perispinal tumor yielded sheets of spindly tumor cells containing abundant **melanin** (Fig. 26-56D).

The presence of **melanin pigment in the cancer cells clinches the diagnosis of malignant melanoma.** The pigment is brown in Papanicolaou-stained preparations and green with Diff-Quik stain (Dade Behring Inc., Deerfield, IL). In some effusions, the pigment is present in virtually every cell; in others, pigment formation is confined to a few cells. It is of interest that

if multiple sequential samples of an effusion of the same patient are studied, **the presence of pigment may vary from sample to sample**. In individual cells, the abundant pigment may obscure the nuclear features essential in establishing the diagnosis. However, this **pigment is not a constant feature** in cells of metastatic malignant melanoma and, **in about 20% of these tumors, the pigment is absent**.

Hajdu and Savino (1973) used **ferric ferricyanide stain** to demonstrate melanin in tumor cells in effusions. **Fontana-Masson stain** may serve the same purpose. **Immunocytochemistry** may also be used to confirm the diagnosis, particularly the antibodies **HMB45** (Longatto Filho et al, 1995), and **MART-1** (Beaty et al, 1997) which give a positive cytoplasmic stain in about 80% of malignant melanomas. For further discussion of immunocytochemistry, see Chapter 45.

Under exceptional circumstances, **melanin pigment may be found in benign cells in effusions**. Allen et al (1997) observed melanin in benign macrophages in a case of **melanosis coli**, discussed in Chapter 25. **Macrophages may store melanin pigment** if the cells of malignant melanoma break down, or in cases of massive melanosis.

P.1005

Hemosiderosis, or accumulation of brown pigment derived from hemoglobin in macrophages in chronic hemorrhagic effusions, **is the most important source of diagnostic error**. The macrophages may be of abnormal shapes, and their nuclear structure, although partly concealed by pigment, may show atypical features, mimicking a metastatic melanoma. Therefore, it is suggested that a simple **stain for iron identifying hemosiderin**, be included as a part of the work-up of samples containing brown pigment, before the diagnosis of metastatic malignant melanoma is made (for further discussion, see Chap. 25).

In spite of these *caveats*, the identification of metastatic melanoma in effusions is possible in

most cases. Few other metastatic tumors in fluids have this variegated and yet characteristic appearance.

CYTOLOGIC PRESENTATION OF SARCOMAS AND OTHER UNCOMMON CANCERS

Sarcomas of Soft Tissues and Bone

A large variety of metastatic sarcomas may produce effusions. The subject has been extensively discussed in the book by Hajdu and Hajdu (1976). Most **sarcomas of soft tissues in fluids tend to form unusual, large, and sometimes bizarre tumor cells**. The exact identification of type of tumor is rarely possible, although there are occasional exceptions. Since it is most unusual for sarcomas to produce effusions as the first manifestation of disease, **knowledge of past history and review of prior histologic material** is very helpful in the determination of tumor type. It must be stressed that the exact classification of many spindle cell sarcomas is often the subject of considerable debate, even on ample histologic material. Hence, it would be unlikely that such difficult diagnostic problems could be solved on examination of a handful of cells in a fluid. Abadi and Zakowski (1998) reviewed 24 effusions containing cells of a variety of sarcomas and listed a number of features that they considered important in the diagnosis: scant cellularity, occurrence of single tumor cells, indistinct cell borders, nuclear pleomorphism, and multinucleation were described as characteristic of this group of metastatic tumors. Unfortunately, all these features can be found in other tumors as well.

Spindle Cell Sarcomas

In histologic sections, the sarcomas of **connective tissue, nerve, smooth muscle, vascular, synovial, or bone origin**

P.1006

are either composed of, or have a large component of, **spindly, elongated cancer cells**. When seen **in fluids**, the tumor cells may remain spindly (see Figs. 26-19 and 26-24) but are often large and nucleated, of polyhedral or of bizarre configuration. The **nuclei** are usually very **large, hyperchromatic, and provided with multiple, large nucleoli**; thus, the identification of malignant disease is usually easy. Figure 26-57 shows a case of metastatic stromal sarcoma of the breast in pleural fluid, characterized by bizarre, multinucleated tumor cells. Further classification of these tumors in fluids is rarely possible.

Rhabdomyosarcomas

These tumors are characterized by the presence of large, bizarre, often multinucleated tumor cells (Hajdu and Koss, 1969). The diagnosis may be established with complete certainty if **cytoplasmic cross-striations are present**. This may occur with **metastatic rhabdomyosarcomas** or with **metastatic uterine mesodermal mixed tumors** that contain a component of rhabdomyosarcoma (see Figs. 17-6, 24-40B). Kaw et al (1984) described a case of a rhabdomyosarcoma in a patient with **germ cell tumor**. The features of **embryonal rhabdomyosarcoma** are described below with effusions in children.

Figure 26-57 Metastatic stromal sarcoma of the breast in pleural fluid. A-C. Bizarre, multinucleated tumor cells with granular nuclear chromatin and nucleoli. The biopsy of the original breast tumor removed 3 years before the metastasis is shown in D.

Leiomyosarcoma

The cancer cells in fluids **rarely retain the elongated form observed in tissue or in gynecologic material** (see Chap. 17). The cells are usually few in number, spherical or oval, with abnormal nuclei, surrounded by scanty, poorly demarcated cytoplasm. Giant cells are very rare (Hajdu and Koss, 1969). In the absence of past history and histologic material, the precise diagnosis of leiomyosarcoma is rarely possible in fluids.

Sarcomas of Bone

Metastatic **osteogenic sarcomas** may produce effusions, usually in the pleural cavity in association with pulmonary metastases in adolescents (Geisinger et al, 1984). These events were frequent in the past, before effective therapy for these tumors had been devised and are nowadays quite rare.

Cytology

Although **bizarre, large cancer cells** may occur, formation of osteoid tissue by these cells has not been seen in effusions. Occasionally, however, **very large, multinucleated giant cells with regular, even nuclei, provided with small nucleoli**, have been observed. **These cells mimic osteoclasts**

P.1007

and have also been observed in **the very rare metastatic giant cell tumors of bone** (Fig. 26-58). These cells are usually much larger than multinucleated macrophages or megakaryocytes. Although the frequency of occurrence of the osteoclast-like cells in effusions has not been determined, they may represent a valuable diagnostic clue. Cytochemical demonstration of **alkaline phosphatase in tumor cells** is diagnostic of osteogenic sarcoma (Fig. 26-58B).

Other Sarcomas

Sporadic case reports on a variety of rare sarcomas in fluids have been personally seen or published. **Kaposi's sarcomas** cause **bloody effusions** wherein **fibroblast-like cells** can sometimes be observed. Other **angiosarcomas** may shed bizarre, elongated malignant cells (see Fig. 26-24). **Malignant fibrous histiocytomas** in effusions did not produce a tumor specific pattern (Abadi and Zakowski, 1998). Geisinger et al (1980) described a case of **pleomorphic liposarcoma**, whereas Nguyen et al (1986) described a case of **clear cell sarcoma** in pleural fluid. Massoni and Hajdu (1984) described a variety of primary and **metastatic uterine sarcomas**. None of these observations or reports indicate cytologic specificity that would allow the diagnosis of these tumor types in effusions in the absence of clinical history or histologic findings.

Figure 26-58 Osteogenic sarcoma in pleural fluid. *A.* A very large multinucleated cell similar to an osteoclast. *B.* A single cell stained for alkaline phosphatase. *C.* Another example of osteogenic sarcoma showing multinucleated bizarre cancer cells corresponding to the tumor shown in *D.*

Rare Metastatic Malignant Tumors in Effusions

Testicular Tumors

The most common testicular tumors capable of forming metastases and effusions are **seminomas**, **malignant teratomas**, and, in the older man, **malignant lymphomas**. **Metastatic seminomas** are characterized by a population of **large malignant cells**, often accompanied by numerous **lymphocytes** (see Chap. 33). **Malignant teratomas** are most often identified in fluids as embryonal carcinomas (see below). The very rare **malignant lymphomas of testicular origin** have a cytologic presentation similar to that of other malignant lymphomas (see above).

Thymoma

Zirkin (1985) described a case of a **metastatic thymoma**, of mixed **lymphocytic-epithelial**

type that caused a pleural effusion six years after surgical removal of the primary tumor. The metastatic tumor in cell block preparations mimicked to perfection the primary tumor, showing nests of

P.1008

large epithelial cells with scanty cytoplasm in an intimate relationship with clusters of lymphocytes. For further discussion of thymomas, see Chapter 37.

Mediastinal Teratoma

Pleural effusion caused by a **rupture** of a **benign cystic mediastinal teratoma** was described by Cobb et al (1985). The fluid contained **benign squamous cells and hair shafts** documenting the dermoid nature of the tumor.

Olfactory Neuroblastoma (Esthesioneuroblastoma)

A metastatic **olfactory neuroblastoma (esthesioneuroblastoma)** in pleural fluid in a 40-year-old man, 6 years after the removal of the primary tumor of the nasal cavity, was reported by Jobst et al (1983). The **tumor was accurately recognized in the fluid** whereas the original histologic diagnosis was that of an adenocarcinoma. **The small tumor cells formed rosettes and cell clusters arranged in an "onion skin" pattern** that was consistent with a neuroblastoma. For a discussion of neuroblastoma in childhood, see below. For a discussion of this tumor in aspiration biopsies, see Chapters 31 and 40.

Merkel Cell Carcinoma

A **neuroendocrine (Merkel cell) carcinoma of the skin** causing pleural effusion in a man age 80, 23 years after treatment of the primary tumor, was described by Watson and Friedman (1985). The **small tumor cells with scanty cytoplasm** and large, hyperchromatic nuclei formed **rosettes and single files**. Neuroendocrine granules were observed in electron microscopy. The **characteristic small eosinophilic cytoplasmic inclusions, abutting on the nucleus**, that were subsequently identified as characteristic of Merkel cell carcinoma in aspiration biopsies (FNA), were not described in the fluid. For further comments on this tumor, see Chapter 34.

Tumors of the Central Nervous System

It is most unusual for tumors of the central nervous system to metastasize to the body cavities. Exceptions to this rule are very few. In most such cases, the tumor cells are transported via a **shunt**, leading from the ventricles of the brain to the abdominal cavity, installed to prevent hydrocephalus in incurable cases.

Endodermal Sinus Tumor (Yolk Sac Tumor) of the Pineal

Peritoneal implants of an **endodermal sinus tumor of the pineal region via a ventricular-abdominal shunt** were reported by Kimura et al (1984). In the ascitic fluid, the small epithelial tumor cells formed **three dimensional aggregates, consistent with the Schiller-Duval bodies**. A similar **tumor of the mediastinum** in pleural fluid was reported by O'Brien and Moinuddin (1990).

Meningioma

A case of metastatic **meningioma** causing a pleural effusion was described by Safneck et al (1998). The metastatic tumor, an extraordinary rarity, produced **meningothelial whorls** of

cells, allowing its recognition. For further discussion of cytology of meningiomas, see Chapter 42.

Ependymoma and Tumors of the Choroid Plexus

Wurtz et al (1995) described a case of **metastatic anaplastic ependymoma** in pleural effusion. The tumor formed the characteristic **pseudorosettes** in a background of peculiar matrix material. McCallum et al (1984) described peritoneal metastases of a **choroid plexus carcinoma** of the brain in a 5-year-old boy with a ventricular-peritoneal shunt. The tumor cells were identified in the ascitic fluid. The cytologic presentation (**rosettes formed by tumor cells**) was similar to ependymoma. For further discussion of cytologic presentation of tumors of the central nervous system, see Chapter 42.

Other Tumors

It is virtually impossible to describe in detail the cytologic presentation of a large number of uncommon metastatic malignant tumors that may be found in effusions. Still, some of these tumors may form cell patterns suggestive of their type and origin although, in most instances, the **knowledge of clinical history and a review of prior or current histologic material** are usually essential in the identification of tumor type.

TWO SYNCHRONOUS MALIGNANT TUMORS IN EFFUSIONS

Patients surviving a malignant neoplasm are prone to second and even third primary tumors. **The second tumors in patients with epithelial cancers are quite often tumors of the lymphoid type. The opposite sequence** may be observed in patients with **chronic lymphocytic leukemia** who have impaired immunity.

Occasionally, the presence of **two tumors may be observed in effusions**. In the example shown in Figure 26-59, synchronous evidence of metastatic primary tumor, a **mammary carcinoma** and a secondary **cleaved cell malignant lymphoma**, both occurring in a 57-year-old woman, is shown. Sur and Silverman (1998) reported a case of a 65-year-old man with chronic lymphocytic leukemia and an adenocarcinoma, presumably of lung origin observed in a pleural effusion.

EFFUSIONS IN CHILDREN

Since 1970, remarkable successes have been achieved in the treatment of most tumors of childhood that were previously considered incurable. Because, in most cases, the effusions occur as a consequence of metastases late in the course of the disease, the frequency of these events has dropped considerably. Still, there are opportunities for the pathologist to contribute to the primary diagnosis or, more often recognize

P.1009

the metastatic spread of these tumors with great benefits for the patient.

Figure 26-59 Synchronous metastatic mammary carcinoma and primary malignant lymphoma in pleural fluid in a 57-year-old woman. *A.* A large cluster of epithelial cancer cells corresponding to mammary cancer. *B.* A large population of lymphocytes with cleaved nuclei corresponding to the synchronous malignant lymphoma.

The variety of malignant tumors in young children, capable of producing effusions, is relatively limited. It is unusual for such tumors to produce effusions before the clinical and histologic diagnosis has been established, thus facilitating the recognition of the tumor type.

By far, the most common neoplasm of childhood is **acute leukemia, usually of the lymphoblastic type**. The principal **solid tumors** in this group are: **Wilms' tumors, neuroblastomas, embryonal rhabdomyosarcomas, Ewing's tumors, and embryonal carcinomas**. Most of these tumors are **made up of small cancer cells** and, because of their common histologic appearance, have been colloquially grouped as “**small, blue cell tumors**.” Most of these tumors are associated with genetic abnormalities and specific chromosomal translocations. The differential diagnosis of these tumors in effusions **must always include lymphomas and leukemias**. The aspiration biopsy (FNA) findings in solid childhood tumors are discussed in appropriate chapters, depending on organ of origin.

Wilms' Tumor

These malignant teratoid renal tumors comprise **elements of adenocarcinoma and sarcomas, the latter most commonly a rhabdomyosarcoma**. The cytologic patterns in effusions are usually characterized by **small, round cancer cells with scanty cytoplasm and large, hyperchromatic nuclei, arranged in small balls or papillary clusters, suggestive of an embryonal carcinoma** (Fig. 26-60A). Occasionally, one may also observe **elongated malignant cells suggestive of a spindle cell sarcoma**. The secure diagnosis rests on this **mixture of cell types which, in a child, is uniquely characteristic of Wilms' tumor**.

Neuroblastoma

These tumors of neural crest origin, **usually originating in the adrenal medulla**, are characterized by **small, round cancer cells**, occasionally arranged in **small aggregates with a central lumen or the so-called rosettes**. In histologic sections and in aspirated material (FNA), **neurofilaments** may be observed in the center of the rosettes. In fluids, the cells of neuroblastoma resemble the small cells observed in Wilms' tumor, described above and shown in Figure 26-60B. The **rosettes**, which, with rare exceptions, are **diagnostic of these tumors**, are uncommon in fluids. The **exceptions** pertain to ependymomas and neuroendocrine tumors,

described above. In the absence of the rosettes, the diagnosis of a **“small cell malignant tumor”** is usually rendered, pending correlation with clinical data.

Ewing's Sarcoma

Ewing's sarcoma usually occurs in bones, although rare examples have occurred in soft tissues but not in children. In effusions, the tumor has a histologic and cytologic presentation very similar to that of a neuroblastoma (see Fig. 26-60C).

Embryonal Rhabdomyosarcomas

Three anatomic sites of these muscle-derived sarcomas are seen almost exclusively in childhood: tumors of the **vagina** in girls, tumors of the **prostate** in boys, and tumors of **bladder** in children of both sexes (recent summary in Leuschner et al, 2001). In all these organs, the tumor may assume a grape-like configuration, hence the name **“botryoid sarcoma”** (see also Chaps. 14 and 23). Embryonal rhabdomyosarcomas of soft parts, derived from **peripheral muscle**, may be seen in children and in adults. In histologic material, the tumors are characterized by **proliferation of small to medium-sized malignant cells, occasionally assuming an organoid pattern (alveolar rhabdomyosarcoma)**. Cytoplasmic cross-striations diagnostic of this tumor are not readily observed, and often one must rely on the finding of **eosinophilic myoglobin deposits in the**

P.1010

wide cytoplasm of the tumor cells (so-called **strap cells**) or on **immunocytochemistry** for diagnosis.

In effusions, the most commonly observed pattern is that of **elongated tumor cells** (Fig. 26-60D). Sometimes the tumor cells are larger, have abundant cytoplasm and may be confused

with an epithelial tumor which, however, is very rare in childhood, except for the embryonal carcinoma, described below.

Embryonal Carcinomas and Endodermal Sinus Tumors

These tumors of various primary anatomic origin (**ovary, testis, anterior mediastinum, sacrococcygeal region**) are seen predominantly in childhood or early adolescence, but they also may occur in adults. Quite often these tumors represent a **unilateral development of complex malignant teratomas**, for example, in the testis or in the mediastinum. In histologic sections, the tumors form gland-like structures.

The cytologic presentation of these tumors in effusions is the same, regardless of anatomic origin. The **tumor cells of moderate sizes, often of monotonous appearance, occur in papillary clusters or singly. The nuclei are provided with conspicuously large, irregular nucleoli.** This cytologic configuration, essentially suggestive of an adenocarcinoma when seen in a young patient, strongly suggests an embryonal carcinoma. In the case of a 9-month-old boy, shown in Figure 26-61, a **primary diagnosis** was rendered by cytologic examination of pleural fluid. Cho et al (1991) described a case of an **endodermal sinus tumor**, located on the surface of the colon and producing ascites in a 3-year-old boy. The ascitic fluid contained three dimensional papillary clusters of malignant cells. For further comments on **yolk-sac tumors**, see ovarian tumors above.

Acute Leukemias and Malignant Lymphomas

Acute leukemia and malignant lymphomas are **the most common group of malignant tumors in childhood responsible for effusions.** The cytologic presentation is similar to that observed in other age groups (see above). The **differential diagnosis** must include the group of tumors composed of “small blue cells,” discussed above, which, however, virtually always produce some **organoid structures (papillary clusters or rosettes)** that are absent in leukemias and lymphomas.

Very Rare Tumors

Letterer-Siwe disease is the highly malignant variant of a group of disorders within the **Langerhans' cell histiocytosis**,

P.1011

that also comprises eosinophilic granuloma of bone and the so-called histiocytosis X. In one such case, it was possible to identify the **tumor cells** in pleural fluid as belonging to the class of histiocytes because of their **striking morphologic similarities to normal macrophages**, including their phagocytic properties (Fig. 26-62).

Figure 26-61 Embryonal carcinoma of testis in ascitic fluid. A-C. Epithelial cancer cells in the ascitic fluid from a 9-month-old boy who was treated for tuberculosis. He also had a testicular mass that was thought to be a hydrocele. The correct diagnosis was established on ascitic fluid. D. An area of testis with embryonal carcinoma. The tumor metastasized widely.

Malignant teratoma of the pericardium, growing chiefly as embryonal adenocarcinoma, could be identified in the pericardial fluid of a 4-year-old child. The smears contained **side-by-side tumor cells suggestive of a carcinoma and clusters of benign bronchial cells**, reflecting the components of the resected teratoma (Fig. 26-63).

PERICARDIAL EFFUSIONS

Accumulation of pericardial fluid may represent an acute threat to the life of the patient because of possible interference with cardiac function or because of cardiac tamponade. Thus, rapid diagnosis and aggressive treatment may prove lifesaving. The cytologic features of pericardial effusions in the absence of cancer were discussed in Chapter 25. Pericardial effusions can also occur in **primary cardiac lymphomas**, described above, as a consequence of primary **malignant mesotheliomas**, discussed in the opening pages of this chapter, or **metastatic cancer**.

In my experience, the **primary sites of metastatic cancer appear to be the same as for the pleural effusions both in men and women**. Numerous examples of metastatic carcinomas have been observed. Yazdi et al (1980) reviewed cytologic findings in 72 patients with positive pericardial effusions to establish the frequency of primary tumor sites as a source of pericardial metastases. **Lung and breast cancer** were the most common carcinomas; **lymphomas and leukemias**, the most common nonepithelial tumors, with **mesothelioma** a close third. Unfortunately, the results were not presented according to the sex of patients. Wiener et al (1991) reviewed their data on 95 patients, approximately equally divided between benign and malignant disorders. Again, lung and breast cancer were most commonly observed but cytologic findings were noncontributory in one third of the cancer patients. On the other hand, in two patients, unsuspected cancer was discovered. Hoda et al (1998) described four patients with metastatic squamous carcinoma causing pericardial effusion.

The cytologic presentation of these effusions is the same as for other body fluids and need not be repeated here.

P.1012

Occasionally, very unusual events may lead to pericardial effusions. Thus, Venegas and Sun (1988) reported a case of a **malignant thymoma causing cardiac tamponade**.

Figure 26-62 Langerhans' cell histiocytosis. *A,B.* Pleural fluid from a 3-year-old child. Note bizarre, large tumor cells and an abnormal mitosis in (*B*). The phagocytic activity of some of the tumor cells suggested a malignant neoplasm of the reticuloendothelial system. *C,D.* Tissue section of lymph node interpreted as malignant reticuloendotheliosis (malignant variation of Langerhans' cell histiocytosis or Letterer-Siwe disease).

Postinfarction chronic hemorrhagic pericarditis may constitute a source of diagnostic error because the **hemosiderin-laden macrophages may be mistaken for cells of malignant melanoma, as happened in one of our patients**. It is a wise precaution to perform an **iron stain** to identify hemosiderin, whenever metastatic melanoma is suspected.

FREQUENCY OF METASTASES IN EFFUSIONS FROM TUMORS OF VARIOUS SITES

It is not uncommon to see an effusion as a primary manifestation of an occult malignant tumor. The most **commonly observed metastatic tumors** in our laboratory in pleural and ascitic fluids are listed **in order of frequency** for **adult men and women** in Tables 26-4 and 26-5. The distribution of tumors **in children** is shown in Table 26-6. In the absence of clinical history, these tables offer some guidance to the most likely origin of malignant cells.

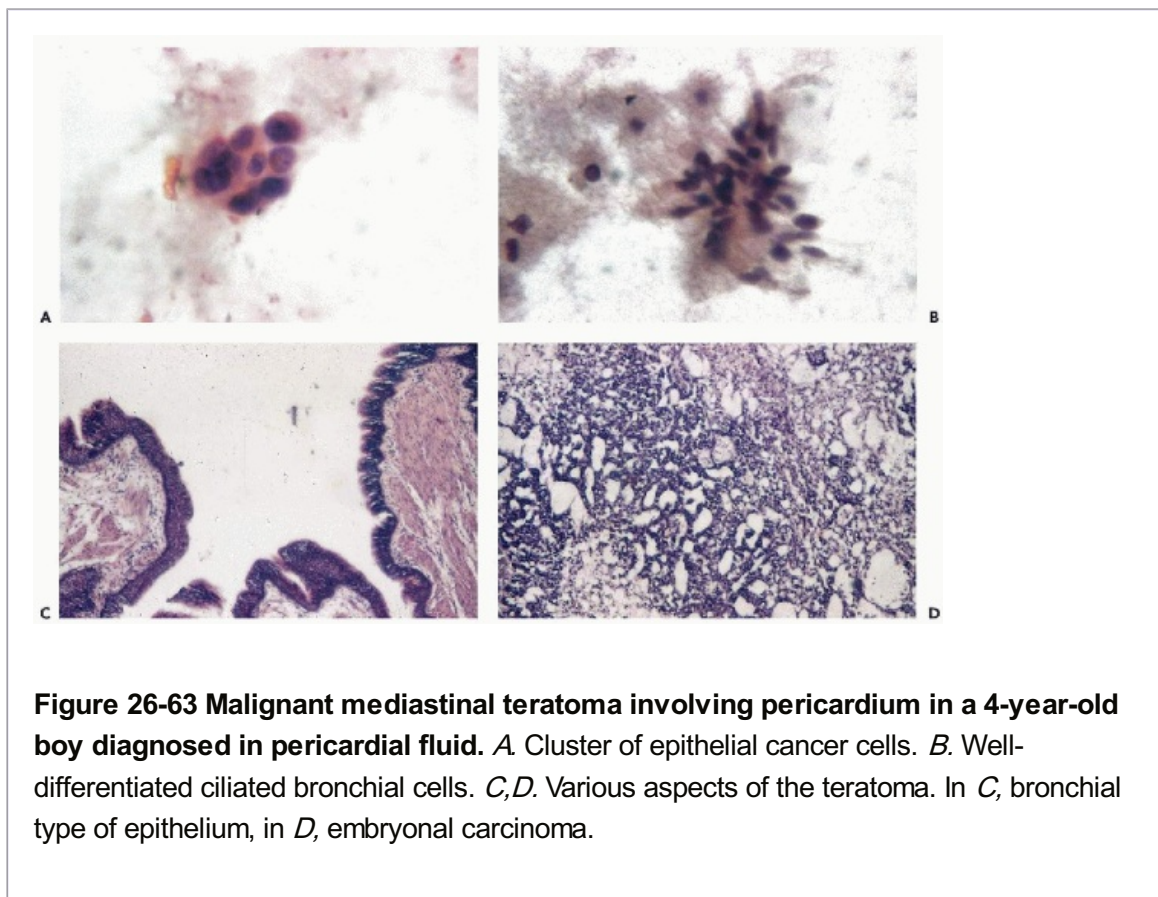

Sears and Hajdu (1987) presented data from the Memorial Sloan-Kettering Cancer Center on

tumor distribution in 3,011 effusions, of which 1,846 were pleural and 1,165 ascitic fluids. Several effusions occurred in both sites. On the average, the effusions occurred 30 or more months after removal of the primary tumor. The dominant sources of cancer for men and women were the same as listed in Tables 26-3, 26-4 and 26-5. A high frequency of malignant lymphomas in both sexes probably reflected the type of patients referred for care to that institution. The paper also included an elaborate listing of rare sources of cancer cells, comprising virtually every organ. Of note was the low frequency of metastatic squamous carcinomas and hepatomas, as discussed elsewhere in this chapter.

DiBonito et al (1992) correlated the findings in malignant pleural effusions with results of autopsies in 143 patients. His observations on distribution of tumor types in men and women were remarkably similar to ours, except for a higher frequency of malignant mesotheliomas in men, perhaps reflecting war-time industrial exposure of patients

P.1013

in the city of Trieste, Italy. It is evident, therefore, that the distribution of tumor types reflects the type of patients referred for care in a given institution.

Helson et al (1975), Hallman and Geisinger (1994), and Wong et al (1997) published comprehensive surveys of their experience with effusions in **children and adolescents**. Further, Wong et al presented a comparison of data from several surveys. All surveys show a remarkable similarity to the distribution of tumors shown in Table 26-5, with leukemia-lymphoma, followed by Wilms' tumors

P.1014

and neuroblastomas, as the most frequent tumors observed.

BODY FLUID CYTOLOGY AS AN INDEX OF RESPONSE OF CANCERS TO THERAPY

Chemotherapy

Since ascitic tumors in animals had long been utilized as a tool in the evaluation of chemotherapeutic agents, it was logical that a correlation of the response of tumor cells in human body fluids with the effectiveness of therapeutic anticancer agents should be attempted.

A sustained, long-term major study of the response of various tumors to radiation and chemotherapeutic agents has not yet been performed. However, some information on this topic is available.

The cells of **malignant lymphomas** in effusions react to either radiation or chemotherapeutic agents with massive **apoptosis (karyorrhexis)**, although this event may also **occur spontaneously** (see Fig. 26-47B). This effect may be so striking that Melamed (1963) considered it as diagnostic of malignant lymphomas and named it the “**nuclear fragmentation pattern**.” This pattern may occur regardless of the type of lymphoma or the therapeutic mode used. The reasons for this type of response are not clear.

Personal anecdotal experience has shown that those **carcinomas in effusions, presenting a marked tissue culture pattern, or a diffuse proliferation of relatively uniform cancer cells, responded better to systematically ministered chemotherapeutic agents than tumors with different patterns of growth**. Among the poor responders were tumors growing in clusters of papillary or glandular type. This observation is somewhat contrary to data discussed above in reference to prognosis of breast cancer in effusions.

A remarkable response has been observed in a case of widespread **ovarian carcinoma** treated with **floxuridine** (5-fluorodeoxyuridine; FUDR). This compound was injected directly into the pleura and the peritoneum and produced **striking mitotic abnormalities** of cancer cells in fluids, resulting in the formation of gigantic, grotesque cell forms (Fig. 26-64). These cytologic changes preceded a sustained clinical remission. Jordan and Wells (1997) reported the effects of **paclitaxel** (**Taxol**, Bristol-Myers Squibb Company, New York, NY) on cells of **ovarian cancer** in ascitic fluid and reported remarkable mitotic abnormalities in cancer cells, caused by microtubule polymerization. We also observed bizarre multinucleated tumor cells in ascitic fluid of a woman treated with Taxol for ovarian cancer with widespread abdominal metastases (Fig. 26-65). These anecdotal observations clearly require additional research to determine the relationship of the reported drug-induced cell abnormalities to the effect of treatment.

Effects of Radiation and Radiomimetic Drugs

The effects of radiation may be observed following either an intracavitary application of radioactive phosphorus or external irradiation treatment. The effects, both on mesothelial cells and on cancer cells, are in essence similar to those observed in other organs and tissue.

Ballooning of cells, cytoplasmic vacuolization, and nuclear enlargement may be noted in the mesothelial cells and the cancer cells. Karyorrhexis observed in malignant lymphomas has been mentioned above. It is rarely observed in other tumors. Similar changes may be observed as a consequence of administration of **alkylating agents**. These observations are anecdotal and should be confirmed in a controlled study.

EVALUATION OF DIAGNOSTIC RESULTS IN EFFUSIONS

This area of application of diagnostic cytology to effusions is among the most difficult to

evaluate objectively. There are several reasons for this, the most important one being the **occurrence of effusions in patients with cancer but not caused by cancer.** Even the comparison of cytologic results with autopsy material may be misleading unless there is no significant delay between the two procedures. Otherwise, in a cancer patient, metastases may develop that did not exist at the time of tapping of the fluid. Consequently, the measure of a good laboratory in this area is not so much the largest possible number of cancers correctly diagnosed, but the smallest number of cancers incorrectly diagnosed.

P.1016

TABLE 26-7 COMPARISON OF DIAGNOSTIC RESULTS OF PLEURAL BIOPSIES AND CYTOLOGY OF PLEURAL FLUID

Patients Studied	
Patients with cancer	72
Patients with cancer and malignant effusion	46
Patients with cancer and benign effusion	26
Patients without cancer	90
TOTAL	162

(Frist B, et al. Comparison of diagnostic values of biopsies of the pleura and cytologic evaluation of pleural fluids. Am J Clin Pathol 72:48-51, 1979.)

Grunze (1964), in a thorough review of this topic, reported correct positive results from various sources ranging from 50 to 90% (Von Haam, 1962). The widely acknowledged work of Saphir (1949) resulted in 80% correct positive diagnoses. It is much more difficult to assess the number of errors. Ceelen (1964) states that no such errors were made in the evaluation of 667 cases, a most commendable performance. Grunze (1964) records three positive errors in 140 patients without cancer whose clinical findings and history were known to him.

A better assessment of performance can be obtained by a simultaneous study of pleural biopsies and fluid cytology, summarized in Tables 26-7 and 26-8, based on work performed at Montefiore Medical Center in New York City by Dr. S. Frist. These results clearly document that, **in malignant disease, the cytologic examination of fluid is by far more accurate than a pleural biopsy.** In infectious diseases, however, particularly in tuberculosis, the **pleural biopsy is superior to cytologic examination** in establishing the etiology of this disorder. Similar data have been provided by Von Hoff and LiVolsi (1975).

Cerebrospinal and Miscellaneous Fluids

CEREBROSPINAL FLUID

CEREBROSPINAL FLUID

Anatomic, Physiologic, and Clinical Considerations

The **cerebrospinal fluid (CSF)** is formed from circulating blood that is filtered through a complex epithelial organ, the **choroid plexus**, located within the ventricular system of the brain. The normal choroid plexus is a highly selective filter that regulates the **chemical make-up** of the CSF and maintains it at a constant level, independently of variations in the blood serum. The choroid plexus is also endowed with genes that **prevent the passage of most toxic substances** into the CSF. No blood cells, except for an occasional monocyte or lymphocyte, cross the choroid plexus, which constitutes a **highly effective blood-brain barrier**, ensuring optimal working conditions for the brain. The CSF is formed by the choroid plexus at a constant rate and is drained by the leptomeninges, resulting in **constant volume of fluid**, at 10 to 60 ml in children, depending on age, and 90 to 150 ml in adults.

Normal CSF is a crystal clear liquid containing only very **few mononucleated blood cells** and **lower levels of glucose and proteins** than the blood serum. The CSF bathes the entire internal ventricular system of the brain, its external surfaces, the cerebellum, and the spinal cord. The **extracerebral CSF is contained between two epithelial meningeal membranes, the pia** (lining the brain) and the **arachnoid (lining the dura)**. Occasionally, **cells** derived from the **choroid plexus, the pia, and the arachnoid** may desquamate into the CSF. Normally, there are very few of these cells and they are difficult to identify.

Any increases in the number of cells in the CSF or changes in the glucose and protein levels invariably indicate a pathologic process. Enumeration and cytologic examination of the cells in the spinal fluid serve to clarify the nature of the disease.

Cytologic examination of the CSF is an important part of a complete neurologic evaluation of cancer patients and patients with the **acquired immunodeficiency syndrome (AIDS)**, particularly if there is clinical evidence or suspicion of central nervous system (**CNS**) involvement. Also, patients with **space-occupying lesions** of the CNS of unknown nature should have the benefit of this examination. **Cytologic evaluation of CSF has become an essential step in the follow-up of patients with lymphoma and leukemia** and some small-cell tumors, such as **oat cell carcinoma of pulmonary origin**, because the therapy of these tumors has been revolutionized by this procedure (see below). An increasingly important application of cytology of the CSF is the **diagnosis of infectious processes**, particularly in patients with AIDS.

Methods of Securing CSF for Laboratory Investigation

Most samples of CSF sent to the laboratory are obtained by **spinal tap** and **this chapter is essentially based on this type of sample**. Another source of CSF is the **cisterna magna** and the **ventricles of the brain**, which are sometimes more informative, particularly in reference to primary brain tumors. Securing such samples requires intervention by a skilled neurosurgeon. Some of the data in the literature are based on a mixture of **samples obtained by various methods**. Whenever possible, these differences are stressed in the text.

Laboratory Techniques

Because the samples of CSF are usually small, rarely more than 10 ml, **impeccable laboratory techniques** are essential if the cytologic evaluation of the fluid is to be successful. Regardless of the method used, cell loss must be avoided. Sedimentation techniques offer the best overview of the cell content. **Hematologic stains and techniques of cell preparation** are helpful in cell identification in samples rich in mononuclear cells, particularly in lymphomas and leukemias. The various technical approaches to the processing of CSF are discussed in Chapter 44. Classification of lymphocytes by **flow cytometry** may be successfully conducted on cell-rich specimens (see Chaps. 31 and 47). **Immunocytochemistry** is occasionally helpful in identifying the origin of metastases in patients with past history of two malignant tumors (see Chap. 45). Various methods of CSF investigation by molecular biologic techniques are described in text.

Figure 27-1 Benign findings in cerebrospinal fluid (CSF) in cytocentrifuge preparations. *A.* Normal CSF contains only a few lymphocytes and monocytes, the latter characterized by more abundant cytoplasm. *B.* CSF containing leukocytes and a large epithelial cell, probably of meningeal origin. *C.* Chondrocytes aspirated from nucleus pulposus. *D.* Powder crystal mimicking cryptococcus (compare with Fig. 27-3).

Special Diagnostic Procedures

Kajikawa et al (1977) used CSF to establish primary shortterm tissue cultures of various primary tumors of the central nervous system. The procedure was successful in a number of instances and the identification of tumor type was easier in the culture than in the original CSF.

Cells and Acellular Components in the Absence of Disease

Cells

With the cell collection techniques used in this laboratory, notably **cytocentrifugation** and Papanicolaou stain (see Chap. 44), only a **very few small lymphocytes and monocytes** are observed in the **CSF of adults**. The monocytes have a **somewhat larger, more open, sometimes indented nucleus** and a slightly **larger rim of cytoplasm**. Thus, only two types of cells and two nuclear forms are normally observed (Fig. 27-1A). By using a careful cell collection technique,

P.1025

Dyken (1975) found that the **cell count is higher in neonates** (less than 1 month in age) **than in older persons**. For the neonates, the average count was 10.17 ± 8.45 cells per cubic millimeter, and for older persons, 2.59 ± 1.73 cells per cubic millimeter. There were also some differences in the differential counts: **monocytes** were the most prevalent cell in neonates, whereas in older persons **lymphocytes** were most commonly observed. In a subsequent study, Dalens et al (1982) confirmed the original observations; in addition, **cells of the choroid plexus and the arachnoid** were noted as a **transient phenomenon during the first week of life**. The presence of these cells is probably caused by slight brain trauma sustained during birth.

In our experience, the identification of **normal cells derived from the brain**, such as choroid plexus and ependymal cells, is extremely difficult in adult patients in CSF obtained by spinal tap. Kline (1962) and Naylor (1961, 1964) described **ependymal cells as small cuboidal cells arranged in rows or clusters**; their occurrence may be expected, mainly in **fluid aspirated directly from the cerebral ventricles or the cisterna magna**, or in **direct samples of the brain**, described in Chapter 39. Wertlake et al (1972) also observed occasional **pia-arachnoid cells, resembling mesothelial cells** and, occasionally, cells interpreted as **astrocytes in ventricular fluid**. **Elongated cells**, described by Kline as originating from **meningeal lining**, have not been observed by us in normal spinal fluid. Kölmel (1976) observed such cells **after pneumoencephalography**. However, we did occasionally observe in cases of meningitis, fairly **large epithelial cells with transparent cytoplasm** and degenerated nuclei that we assumed were of meningeal origin (Fig. 27-1B). The cytologic-histologic correlation of these rare cells has been carried out by McGarry et al (1969).

Bone marrow cells may be observed when the tap needle inadvertently enters a vertebral body. **Megakaryocytes** are usually a conspicuous component of such faulty taps.

Chondrocytes (Fig. 27-1C) occur when the tap needle incidentally enters the intervertebral cartilage (Bigner and Johnston, 1981; Takeda et al, 1981). **Notochordal cells from nucleus pulposus** have been observed in an infant (Takeda et al, 1981). Such cells may **mimic a chordoma** (see below). **Squamous cells and anucleated squames** are rare in CSF and are usually of **skin** origin. Important, but extremely rare sources of squamous cells are a **ruptured benign squamous cyst of the brain, a craniopharyngioma, or metastatic squamous carcinoma**.

Acellular Components

Corpora amylacea, spherical transparent proteinaceous structures, commonly seen in the brain of the elderly, may occasionally occur in the CSF (Bigner and Johnston, 1981). They are sometimes calcified and **mimic a psammoma body or a fungus** (Preisig and Buhaug, 1978).

Powder Crystals

Cerebrospinal fluid may be contaminated by starch granules from powder used on surgical gloves. In a personally observed consultation case, the approximately spherical **crystals were mistaken for spores of the fungus *Cryptococcus neoformans***, described below (Fig. 27-1D). Such particles may be phagocytized, as reported by Reinharz et al (1978). In polarized light, the starch particles form a Maltese cross but this may also occur with *Cryptococcus*. In general, **starch particles are larger than *Cryptococcus***, and often show a **central density**, but **fail to show budding or mucous capsule**.

Changes in Benign Cell Populations in Disease

Under pathologic conditions, several changes in the benign cell population of the CSF may take place.

Increase in Cellularity

A mere increase in the number of leukocytes and macrophages **always** reflects a **pathologic process** affecting the cerebrospinal fluid. The lesion may be in the brain or in the meninges. Changes in protein and glucose content of CSF often accompany the increased cellularity.

Transformation of Lymphocytes and Monocytes

Under a broad variety of circumstances, such as **viral meningitis** and most forms of chronic inflammation such as **tuberculous meningitis**, lymphocytes increase in number and may undergo a **transformation that increases substantially the variety of lymphoid cells**. These cells range in size from small lymphocytes to large cells, resembling **immunoblasts**, with a **clear nucleus and large nucleolus**. The **monocytes** may be transformed into **macrophages** and may assume a phagocytic activity (Fig. 27-2A). Oehmichen (1976) characterized mononuclear phagocytes in CSF using membrane markers. Newer methods of classification of mononuclear cells will be described as needed.

Polymorphonuclear Leukocytes

These cells normally do not cross the blood-brain barrier; hence, they must be considered as invaders of the CSF. **The presence of neutrophilic polymorphonuclear leukocytes in CSF always indicates an acute inflammatory process**, such as **bacterial meningitis, brain abscess**, some forms of **viral encephalitis**, or sometimes a **reaction to intrathecal chemotherapy**. The cells most likely are derived directly from damaged blood capillaries located within the brain or the meninges.

Eosinophils may occur in CSF as a consequence of a **parasitic infection** of the central nervous system (*Cysticercus cellulosae* cysts, see below), in chronic inflammations, or as a **reaction to trauma**. The condition is extremely rare in my experience. Conrad (1986) observed **eosinophils in metastatic cancer and in children with a shunt**. We have seen such cells in granulocytic sarcoma (see below).

Red Blood Cells and Hemosiderin

Erythrocytes do not normally cross the blood-brain barrier. The most common source of erythrocytes in CSF is a **traumatic tap, surgical intervention, trauma, or brain hemorrhage**. The presence of **hemosiderin-laden macrophages**, on the other hand, indicates a previous **hemorrhagic event**. This may be caused by a cerebral or subdural hemorrhage or the presence of a tumor. Bernad and Taft (1980)

P.1026

documented that the presence of numerous **hemosiderin-bearing macrophages** was consistent with an intraventricular hemorrhage in a neonate. In appropriate cases, an **iron stain** should be performed to differentiate **hemosiderin from melanin pigment**. **Macrophages containing melanin** have been observed in **melanosis of the meninges** (Rosenthal, 1984) that must be differentiated from hemosiderin-bearing cells or cells of primary or metastatic malignant melanoma (see below).

Figure 27-2 Benign disorders in CSF. A. Two large macrophages with vacuolated cytoplasm observed after a myelogram. B. *Klebsiella* filament and neutrophils from an acute meningitis. C. Increased population of lymphocytes and monocytes in a patient with chronic meningitis of unknown ideology. D. Chronic meningitis, presumably caused by tuberculosis. There is a dense mixed population of lymphocytes, monocytes, and scattered macrophages. (B: High magnification; courtesy Dr. Ellen Greenebaum, College of Physicians and Surgeons, Columbia University, NY.)

Plasma Cells

The presence of plasma cells in CSF **always** indicates an important abnormality. This may be a **neurologic disorder, a chronic inflammatory event, or plasma cell myeloma** (see below).

Cytology in Specific Nonmalignant Disorders

Effects of Myelograms

The injection of a radiopaque medium into the spinal canal results in activation of **monocytes into macrophages** (Fig. 27-2A). The large cells with round or kidney-shaped nuclei and

vacuolated cytoplasm increase in number, become quite conspicuous, and often contain **phagocytized deposits of the yellow radiopaque material**.

Acute Bacterial Meningitis

Cerebrospinal fluid in meningitis caused by ***Neisseria meningitidis*, *Haemophilus influenzae*, pneumococci, or other pyogenic organisms**, is characterized by the dominance of numerous neutrophilic polymorphonuclear leukocytes. The **glucose** content of CSF is **reduced** and the **protein level** is markedly **elevated**. Some offending organisms, such as *Klebsiella*, can sometimes be recognized (Fig. 27-2B).

Viral Meningitis and Meningoencephalitis

Viral (aseptic) meningitis may be caused by a variety of RNA or DNA viruses.

The initial cytologic abnormality, usually of a very short duration (1 or 2 days) is the presence of **neutrophilic leukocytes** (Kölmel, 1976). The neutrophils are rapidly replaced by a population of **activated lymphocytes** and some plasma cells that may **vary in numbers** but this variability is not indicative of any specific viral type (Fig. 27-2C). Kölmel (1976) reported the highest counts (3,000 cells per mm³) in **Coxsackie virus meningitis** and the lowest count (40 cells per mm³) in **herpes zoster meningitis**. As the disease process progresses, there is an **increase in monocytes and macrophages** (Fig. 27-2D). With healing, the cell count returns to normal.

P.1027

It is of interest that the **sequence of cellular events** in CSF (**neutrophilic phase to lymphocytic phase to macrophage phase**) is similar in all inflammatory afflictions of the meninges, regardless of etiology (see below). The lymphocytic picture of viral meningitis may cause problems in the **differential diagnosis of malignant lymphoma** and may require a flow cytometric or immunocytochemical analysis of the lymphocytes (Moriarty et al, 1993; Windhagen et al, 1999).

Tick-Borne Encephalitis

This is a serious CNS disorder, prevalent in central and Eastern Europe. The disease is caused by **arboviruses**, transmitted from wild animals to humans by ticks. Jeren and Vince (1998) studied the make-up of the **CSF** in this disease by morphologic and immunocytologic analyses. They observed that, during the **first 3 days** of the illness, there was a **prevalence of polymorphonuclear leukocytes**, accompanied by a few eosinophiles and basophiles. During the **second week** of illness, the leukocytes were replaced by lymphocytes and macrophages. Jeren and Vince documented that the **prevalent lymphocytes were T-cells** (CD3 positive), whereas B-cells (CD20 positive) and macrophages (CD32 positive) were in the minority. Of the T-cells, most were suppressor cells (CD8 positive), with a lesser population of helper cells (CD4 positive).

La Crosse Encephalitis

This sometimes fatal illness occurring in childhood is caused by a mosquito-transmitted virus, first isolated in La Crosse County, Wisconsin (McJunkin et al, 2001). The disease may **masquerade as a viral meningitis or herpetic encephalitis** and the diagnosis requires identification of the virus. The cerebrospinal fluid shows an **increase in lymphocytes** in most, but not all, cases and, hence, the cytologic findings are not specific.

Herpes Simplex Encephalitis

Encephalitis caused by infection with herpes simplex virus type I or II is characterized by **hemorrhagic necrosis of the brain** (review by Crumpacker et al, 2003). Gupta et al (1972) were the first to observe the **characteristic virus-induced inclusions** in cells in CSF. For the detailed descriptions of the herpes virus-induced cellular changes, see Chapter 10.

Progressive Multifocal Leukoencephalopathy

This disorder, caused by infection with **human polyomavirus type JC**, is discussed at length in Chapters 22 and 39. This previously rare brain disease has increased markedly in frequency with the onset of AIDS (recent summary in Greenlee, 1998). The characteristic **homogeneous basophilic nuclear inclusions** in oligodendrocytes and astrocytes have not been reported in CSF. However, the presence of the JC viral DNA may be documented by **polymerase chain reaction (PCR)** of CSF (Fong et al, 1995). D'Arminio Monforte et al (1997) documented that PCR of CSF is at least equal to brain biopsies in the diagnosis of this essentially incurable disorder.

Tuberculosis

After a lull of several years, tuberculous meningitis is being seen again with increasing frequency, in part because of the **AIDS** epidemic. The cytologic picture is not specific and depends on the stage of the disease. In **early stages**, the CSF is very rich in cells, initially neutrophilic leukocytes, followed by **transformed lymphocytes, plasma cells, and activated macrophages** (see Fig. 27-2D). The changes in cell population are accelerated by therapy (Jeren and Beus, 1982). The presence of **multinucleated giant cells** has been noted (Kölmel, 1976) but this finding is nonspecific. For example, Bigner et al (1985) observed **multinucleated giant cells in CSF as a reaction to foreign material** introduced during surgery and in a patient with **sarcoidosis**.

Fungal Meningitis

The most common fungus causing meningitis, particularly in immunocompromised or debilitated patients, is ***Cryptococcus neoformans***. This was the most common agent identified in adults in a review of nearly 6,000 spinal fluid samples by Prayson and Fischler (1998). The **round or oval yeast organisms**, measuring from 4 to 10 µm in diameter, are provided with a **thick, mucoid capsule** that can be easily visualized by lowering the condenser of the microscope (Fig. 27-3A). The diagnosis can be **confirmed** by a number of **mucus stains** [mucicarmine, periodic acid-Schiff (PAS); Fig. 27-3B], by a silver stain (Fig. 27-3C), or an India ink preparation. The organism can also produce **single, tear-shaped spores** and may form hyphae (see Fig. 27-3C, see Chap. 19).

The microscopic diagnosis of the mature organism is comparatively easy, the only possible **source of confusion** being **grains of powder** derived from surgical gloves (see Fig. 27-1D). **Meningeal cryptococcosis** causes only a **minimal cytologic reaction** in CSF: the organisms are accompanied by a scattering of mature lymphocytes and an occasional macrophage.

In **immunocompromised hosts**, such as patients with AIDS or patients undergoing intensive chemotherapy, meningitis caused by other fungi can be observed. Thus, ***Candida albicans*** (moniliasis), ***mucormycosis*** (zygomycosis, phycomycosis), and ***aspergillosis*** have been observed. Undoubtedly, other fungi will be observed with the passage of time. For a detailed

description of fungi, see Chapters 10 and 19. For toxoplasmosis, see Chapter 39.

Lyme Disease

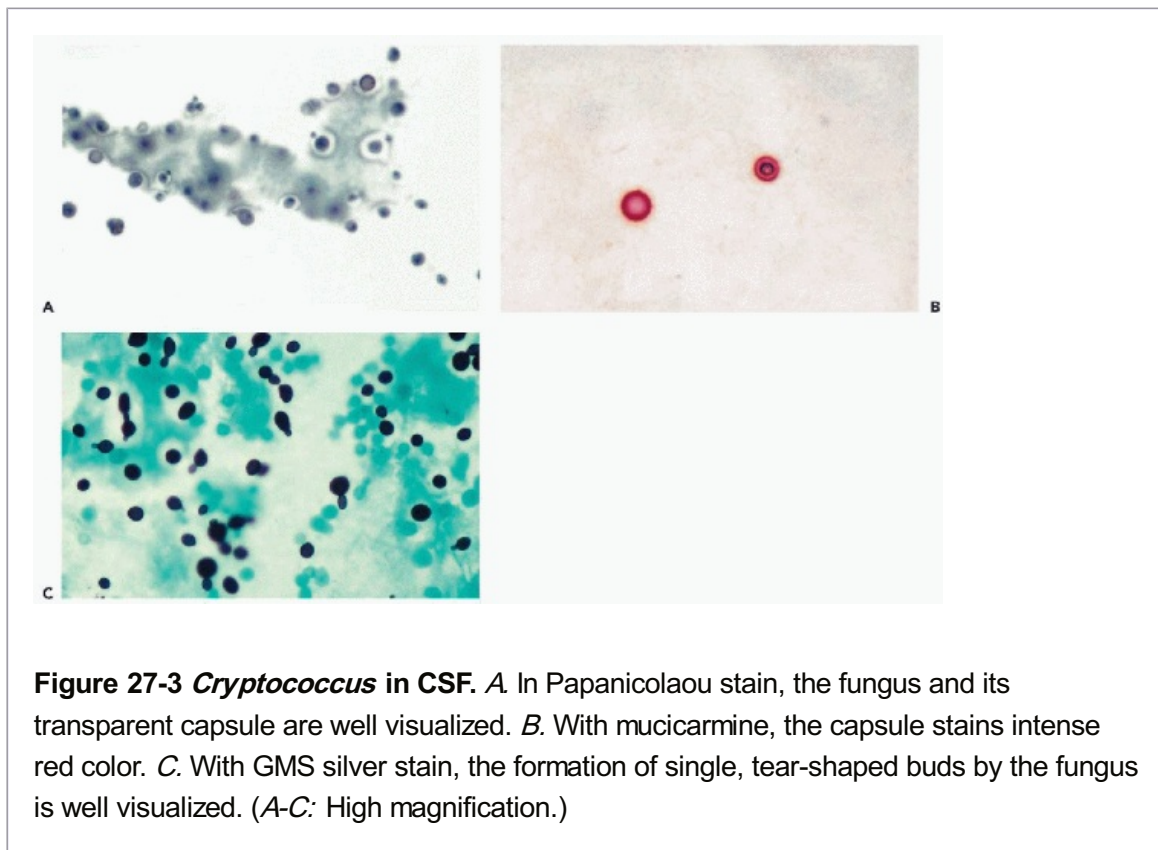

Lyme disease, an ubiquitous infection with the tick-transmitted spirochete, *Borrelia burgdorferi*, may cause meningitis. The CSF may show **marked hypercellularity with activated lymphocytes in all stages, plasma cells, and macrophages** (Benach et al, 1983; Steere et al, 1983; Razavi-Eucha et al, 1987).

Mollaret's Meningitis

This exceedingly rare form of **periodically recurrent aseptic meningitis** of unknown etiology has a very characteristic cytologic presentation in CSF (Gledhill et al, 1975; Mollaret, 1977; Lowe, 1982; Chan et al, 2003). During the acute phase, the CSF has a **very high and variegated cellular content** with numerous polymorphonuclear leukocytes,

P.1028

monocytes, plasma cells, and lymphocytes. The **dominant cells**, however, are **large mononucleated (monocytoid) cells** with abundant cytoplasm and **peculiar nuclei, resembling footprints in the sand** (Fig. 27-4A,B). To observe these cells, the fluid should be obtained within 24 hours after onset of the episode of meningitis (Chan et al, 2003). These cells disappear rapidly from the CSF, hence, they are considered to be fragile. Mollaret thought that these cells were possibly of endothelial origin, but their derivation is most likely from transformed monocytes, capable of phagocytosis (see Fig. 27-4C) (Gledhill et al, 1975; Lowe, 1982; Chan et al, 2003). Teot and Sexton (1996) supported the monocyte/macrophage lineage of Mollaret cells by immunocytochemistry. The presence of **herpesvirus simplex DNA** in this disease has been suggested by polymerase chain reaction (Yamamoto et al, 1991) but could not be confirmed by Teot and Sexton (1996). Chan et al (2003) observed herpesvirus simplex by PCR in 2 of 14 patients.

Lowe (1982) discussed the **differential diagnosis of Mollaret's meningitis** in CSF by citing the findings in a number of very **uncommon systemic disorders with incidental meningitis (Behçet's, Vogt-Koyanagi, and Harada's syndromes)**. The reader is referred to specialized sources for further discussion of these very rare events (Hermans et al, 1972).

Other Rare Forms of Meningitis

Sporadic case reports of unusual cytologic findings in CSF in patients with systemic disorders and secondary involvement of the CNS appear from time to time in the literature. Thus, Jaeckle (1982) described the presence of numerous **macrophages phagocytosing hemosiderin** in a case of **systemic lupus erythematosus** with transient blindness (Anton's syndrome). De la Monte et al (1985) observed a polymorphous cell population (transformed lymphocytes, plasma cells, large atypical mononuclear cells) in patients with **Sjögren's syndrome** with CNS involvement.

Chemical Meningitis

Chemical meningitis is caused by chemical substances such as **chemotherapeutic agents** injected into the CSF. Under these circumstances, the CSF is sometimes examined by cytologic methods. In an occasional case, **polymorphonuclear leukocytes and activated macrophages** can be observed. In a personally observed patient **with metastatic mammary carcinoma** treated with intrathecal methotrexate, **enlargement and cytoplasmic vacuolization** were observed in cancer cells in CSF (see below).

Endometriosis

In a personally observed case, periodic headaches synchronous with menstrual bleeding in a 32-year-old woman, were caused by a focus of **meningeal endometriosis**. In the CSF, clusters of typical **endometrial glandular cells** were observed. The tap also contained red blood cells and hemosiderin-laden macrophages (Fig. 27-5A,B).

Langerhans' Cell Histiocytosis

The finding of large mononuclear cells with nuclear grooves ("coffee bean nuclei"), common in this disorder, was reported

P.1029

in CSF by Ghosal et al (2001). For further comments on this disorder, see Chapters 19, 26, and 31.

Figure 27-4 Mollaret's meningitis in a 48-year-old man with recurrent bouts of transient meningitis: cerebrospinal fluid. *A.* Papanicolaou-stained sediment characterized mainly by the large, mononucleated (monocytoid) cells, with peculiar nuclei of uneven width, resembling footprints. *B.* The footprint image is enhanced in air-dried smears with high magnification, stained with May-Grunwald-Giemsa stain. *C.* The monocytoid cells are capable of engulfing other cells (*arrow*), hence of phagocytic activity. Numerous polymorphonuclear leukocytes, lymphocytes, and plasma cells complete the cytologic picture. (*A,B:* High magnification.) (Courtesy of Dr. D. N. Ferguson. From Lowe, E. Mollaret's meningitis. A case report. *Acta Cytol* 26:338-340, 1982.)

Syringomyelia

Courtesy of Dr. Robert Hutter, highly atypical cells of unknown origin or significance were observed in cerebrospinal fluid in a case of syringomyelia, a congenital malformation of the spinal cord with progressive cystic dilatation of central canal. The fluid was presumably aspirated from the central canal (Fig. 27-5C,D).

Neurologic Disorders

Guillain-Barré Syndrome

This is an acute, progressive form of neuropathy of unknown etiology. The CSF is characterized by an **increase in proteins without increase in cell population**. Nyland and Ness (1978) observed an occasional increase in CSF lymphocytes. We observed a case of meningitis in a patient thought to have a Guillain-Barré syndrome with markedly increased cellularity. The sediment was composed of lymphocytes and numerous macrophages. The possibility that the patient had synchronous meningitis caused by a viral infection could not be ruled out.

Multiple Sclerosis

Multiple sclerosis is a chronic disorder in which **loss of myelin** occurs in plaques, affecting the white matter in the brain and the spinal cord. The disease, lasting many years and more often affecting young women than men, goes through stages of exacerbation and remissions. The disease is generally considered to be an autoimmune disorder, although the exact pathogenesis has not been determined as yet. There is extensive neurologic literature on the significance of cytologic observations in CSF in multiple sclerosis (summary in Andersson et al, 1994). Zeman et al (2001) described **quantitative and qualitative cytologic changes occurring in CSF** during the course of the disease. Briefly, the cell counts were only slightly elevated in nearly all patients, regardless of stage of disease. The cell population consisted of activated and inactive **lymphocytes** and **macrophages whereas neutrophilic leukocytes have never been observed**. Of particular interest was the presence of “**foam cells**” or phagocytic macrophages and **lipophages**, that is, macrophages ingesting fragments of myelin, staining for fat. Also of note was the presence of immature and mature **plasma cells**. There is no persuasive evidence that the cell counts or cell population is of prognostic value. The counts were lower in treated patients but variations may occur spontaneously in the course of the disease. **Fragments of myelinated nerves** have been observed by us in CSF from a young woman, during a severe, debilitating relapse of the disease (Fig. 27-6A,B). This appears to be a unique observation that has not been reported before.

Fluid From Ventricular Shunts

Cerebroabdominal shunts are used to alleviate intracranial pressure and reduce hydrocephalus. Bigner et al (1985) described

P.1030

the cytologic finding in the CSF in three patients. **Foreign body giant cells, papillary fronds derived from the choroid plexus and, in one case, tumor cells from a malignant pineal germinoma**, were observed. In one **ascitic fluid** sample, fragments of **choroid plexus** were noted. McCallum et al (1988) also identified cells of the rare **choroid plexus carcinoma in ascitic fluid** of a 5-year-old child with a shunt. Kimura et al (1984) described peritoneal implants of an **endodermal sinus tumor of pineal origin** (see Chap. 26).

Figure 27-5 Various unusual benign disorders in CSF. *A,B.* Endometriosis. Note clusters of typical glandular endometrial cells. Note cytoplasmic vacuoles in some of the cells. *C,D.* Syringomyelia; bizarre cells with vacuolated cytoplasm in spinal fluid. (*C,D:* Courtesy of Dr. Robert Hutter.)

Cancer Cells

An obvious condition for a **successful cytologic diagnosis** of a primary or metastatic malignant tumor is the **seeding of tumor cells into the subarachnoid space or into the**

P.1031

cerebral ventricles. Even in lesions that are in contact with CSF, the number of malignant cells observed may be very small; the **diagnosis may have to rest on the presence of a dozen, or sometimes fewer, malignant cells.** However, in this particular setting, **even a single abnormal cell should be most carefully evaluated as it may prove to be of diagnostic value.** The sources of error are relatively few and rarely of importance.

Only in **malignant lymphomas and leukemias** and the exceedingly rare **primary meningeal**

sarcomas are abundant cancer cells consistently present in CSF. In other malignant tumors, the presence of **abundant cancer cells** in CSF almost invariably indicates an extensive involvement of leptomeninges (**meningeal carcinomatosis**).

Primary Tumors of the Central Nervous System

For description, classification, and cytologic presentation of tumors of the central nervous system, see Chapter 39. Few of the primary brain tumors involve or spread to the meninges, **except medulloblastoma and related tumors of childhood** (see below). On the rarest occasions, **high-grade astrocytomas may metastasize to the meninges** and the **extracranial lymph nodes**. Pasquier et al (1980) described two such cases and summarized more than 70 similar cases from the literature. Additional examples were cited and illustrated by Kölmel (1976).

Thus, **the CSF is rarely studied as a means of diagnosis of primary brain tumors in adults and the cytologic observations may be considered incidental.** In fact, much of the writing on this subject is based on touch preparations of biopsy fragments or on **CSF obtained after surgery** (Watson and Hajdu, 1977). Naylor's data (1964) also suggest that the **cerebrospinal fluid, obtained directly from cerebral ventricles or the cisterna magna**, is a better medium of diagnosis than spinal tap. Nonetheless, occasionally an **unexpected diagnosis of a primary brain tumor** can be suggested (or confirmed) on **cytologic examination of the CSF** and this is the purpose of this brief synopsis. Several major reviews of this subject have been published by Kline (1962), Naylor (1964), Gondos and King (1967), Watson and Hajdu (1977), Bigner and Johnston (1981), Ehya et al (1981), and Rosenthal (1984).

The recognition of cells originating in the **primary neoplasms** of the CNS in CSF depends on two factors: **anatomic location and degree of differentiation**. Tumors located within the depths of the brain or the spinal cord, and thus not bathed by CSF, cannot be recognized except by direct sampling. **Well-differentiated tumors (astrocytomas grade I and II, or choroid plexus tumors) cannot be recognized in spinal fluid, except as "unusual" or "foreign" cells** (i.e., cells that are not normally observed). For example, cells from **ependymomas** usually appear as **benign cuboidal or columnar cells**. Tumors that shed **recognizable cancer cells (such as astrocytomas of high-grade, glioblastoma multiforme, medulloblastomas and related tumors, or malignant tumors of the pineal)** may be **occasionally recognized in CSF**. The cytologic presentation of the most common primary tumors of the CNS in CSF follows.

Low-Grade Astrocytomas (Grades I and II)

These tumors of glia shed very few, if any, cells into the CSF and we have not seen an example of it. According to the published reports, the tumor cells are **spindly**, although occasionally, **stellate cytoplasm** may be observed. The nuclei are pale, not enlarged, and cannot be recognized as malignant. In fact, Bigner and Johnston (1981) pointed out that **identical cells may be observed in benign destructive processes of the brain**. Watson and Hajdu (1977) recognized only one such tumor in the CSF.

High-Grade Astrocytomas and Glioblastoma Multiforme

The CSF may contain a few abnormal cells with nuclear enlargement and hyperchromasia. In the absence of clinical history, an accurate diagnosis is unlikely. In one of the personal cases of

glioblastoma multiforme, the CSF contained a moderate number of large cells, some with eosinophilic and some with transparent cytoplasm and large single nuclei with prominent nucleoli (Fig. 27-7A). The appearance of the cells was suggestive of a metastatic epithelial tumor rather than a malignant glioma. However, a review of the corresponding tissue sections suggested that these cells were most likely abnormal astrocytes (Fig. 27-7B). **Multinucleated giant tumor cells**, so characteristic of this tumor in tissue, were not seen by us in CSF. When observed, they are strongly suggestive of this neoplasm (Kölmel, 1974). The diagnosis of a primary high-grade brain tumor in CSF should be made only in the presence of confirmatory clinical and roentgenologic evidence. An important caveat is in order here: **the presence of numerous conspicuous cancer cells in CSF is much more likely to represent a metastatic tumor than a high-grade glioma.**

Oligodendroglioma

Watson and Hajdu (1977) described the cytology of this tumor in a touch preparation as made up of **uniformly round cells with round and eccentric nuclei provided with nucleoli**. This is the appearance of these cells in touch preparations seen in our laboratories (see Chap. 39).

Ependymomas

Ependymomas, and their cytologic presentation in direct brain samples, are discussed in Chapter 39. These tumors may occasionally shed cells in the CSF. In a personally observed case of recurrent "cellular ependymoma" in a 19-year-old man, the CSF contained small cells with relatively large hyperchromatic nuclei, occurring singly or in small clusters (Fig. 27-7C,D). None of the characteristic features of ependymoma (cuboidal or columnar cells in palisade-like arrangement or rosette formation) were observed in this case.

Midline Tumors

For a discussion of histology and cytology of this group of tumors, see Chapter 39. Only **germinomas can be recognized**

P.1032

in CSF. Thus, Ginhorst and Tskahara (1979) described a case of recurrent pineal germinoma with pulmonary metastases in which **large tumor cells were recognized in CSF and in sputum**. Of note was the elevation of the beta subunit of **human chorionic gonadotropin** in CSF. Several additional cases of germinomas with cells in CSF have been described (Zaharopoulos and Wong, 1980; Bigner and Johnston, 1981; Geisinger et al, 1984). In patients with **germinomas and other highly malignant tumors treated with an abdominal shunt**, the cancer cells may also be recognized in **ascitic fluid** (see Chap. 26).

Figure 27-7 Primary brain tumors in CSF. *A.* Bizarre epithelial-like cells in spinal fluid in a case of glioblastoma multiforme, shown in *B.* *C.* A cluster of small cells in the CSF in a case of ependymoma, shown in *D.*

Medulloblastomas and Related Tumors

Medulloblastomas occur mainly in the **cerebellum of children** and **young adults**. The tumors are related and morphologically similar to neuroblastomas and retinoblastomas, are highly malignant and **consistently spread to the meninges**, and may also form **distant metastases** (see Fig. 27-8D). After leukemia, this is the most common malignant tumor of childhood that can be recognized in CSF (Prayson and Fischler, 1998). For further comments on the structure of medulloblastomas, see Chapter 39.

Cytology

In CSF, the **cells of medulloblastoma are usually numerous and readily identified as malignant**. The **cells vary in size**. They are **larger in some tumors than in others**, but within each tumor, remain fairly monotonous (Fig. 27-8A,B). The cancer cells may occur singly, in **small clusters**, and may form **rosettes** (Fig. 27-8C). The cytoplasm is scanty, readily visible, and is sometimes elongated. The **nuclei are hyperchromatic**. **Prominent nucleoli** are clearly visible in well-fixed and well-stained material. Such cancer cells **cannot be distinguished from cells of metastatic retinoblastoma** (Fig. 27-9A,B), or embryonal carcinoma, and **when occurring singly, may mimic a malignant lymphoma** (see below). Still, in fortuitous cases, cells of **neuroblastoma** may show **cytoplasmic filaments** (see Fig. 27-9A).

Choroid Plexus Tumors

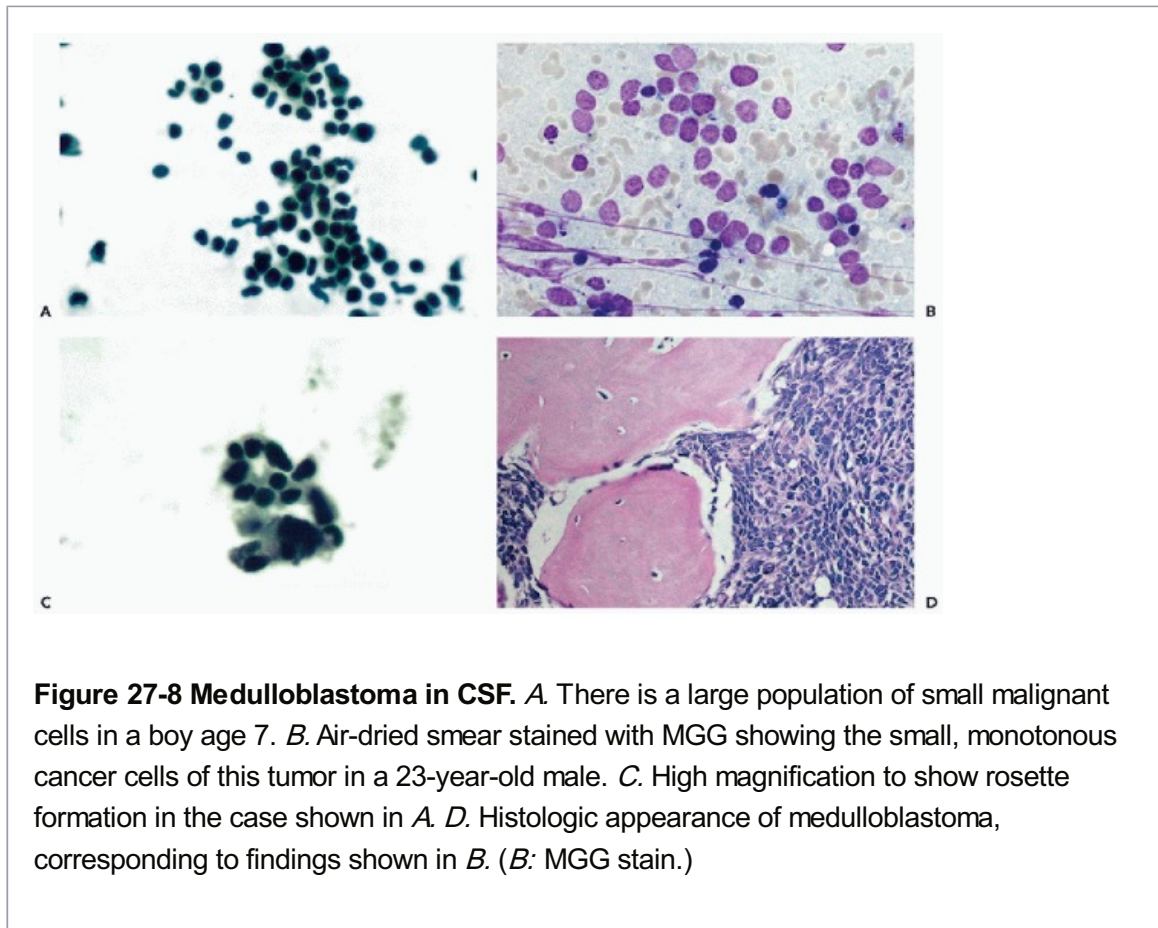

The rare **choroid plexus papillomas** and **carcinomas** may also be identified in CSF. The **papillomas** sometimes shed **cohesive clusters of epithelial cells in papillary arrangements**. The cells of **carcinomas** have the features of any **adenocarcinoma**, with large nuclei and prominent, large nucleoli (Bigner and Johnston, 1981; Kim et al, 1985). As always, when confronted with large cancer cells in CSF, the **differential diagnosis with**

metastatic cancer must be considered. Clinical and roentgenologic data are essential in the interpretation.

Spindle Cell Sarcomas

Spindle cell sarcomas of the brain are **very rare**, difficult to classify, and highly malignant. We have observed one such case with obvious cancer cells in CSF in a patient with a recurrent tumor (Fig. 27-10). The **cancer cells had no distinguishing features** and could have been mistaken for cells of metastatic carcinoma because of abundant cytoplasm.

P.1033

Figure 27-10 Cerebrospinal fluid in a 27-year-old man with recurrent spindle cell sarcoma of the cerebellum, previously treated by surgery and radiotherapy. *A,B.* Clusters of obvious, large cancer cells in CSF. The configuration of the clusters is more suggestive of a carcinoma than a sarcoma. *C.* Biopsy of primary tumor showing a spindle cell sarcoma.

Primary Malignant Lymphomas of the Brain

These tumors are seen with increased frequency in AIDS patients (see Chap. 39). The cytologic presentation of lymphomas is described below.

Squamous Carcinoma

A case of primary intracranial squamous carcinoma **derived from an epidermoid cyst at the base of the brain**, was described by Bondeson and Falt (1984), who observed keratinized cancer cells in CSF. Cells of a **ruptured craniopharyngioma** resemble squamous cancer cells (see Chap. 39). See comment on metastatic squamous carcinoma below.

TABLE 27-1 CEREBROSPINAL FLUID: DIAGNOSTIC RESULTS WITH SOME PRIMARY TUMORS OF THE CENTRAL NERVOUS SYSTEM EXPRESSED AS PERCENTAGE OF POSITIVE RESULTS

Diagnosis	Gondos and King (%)	Watson and Hajdu (%)	Bigner and Johnston ++ (%)
Astrocytoma, grades I and II	25	30 [*]	21
Astrocytoma, grades III and IV	28.6	42+	35

Medulloblastoma	61.9	72	64
Ependymoma	23.1		22
Meningioma	0.0		12

The pathology of cerebrospinal fluid. II. Metastatic cancer, meningeal carcinomatosis, and primary central nervous system neoplasms. Acta Cytol 25:461-479, 1981, based on data published by Bischoff [1961], Kline [1962], Naylor [1964], Gondos and King [1976], and Balhuizen [1978].</p>			

Results of Cytologic Examination

It is very difficult to gain a comprehensive picture of the performance of CSF cytology obtained by **spinal tap** in the diagnosis of tumors of the CNS. Most authors combine primary and recurrent tumors and do not clearly separate the results based on spinal tap from specimens obtained by direct tapping of the cisterna magna, the ventricles of the brain, or even touch preparations of biopsies. The data from three surveys are summarized in Table 27-1. Although about 25% of tumors of the CNS have been reported as

P.1035

yielding diagnostic cells in CSF, it has been **our experience that the diagnosis of brain tumors in routine spinal tap fluids is very uncommon.**

Primary Tumors of Meninges

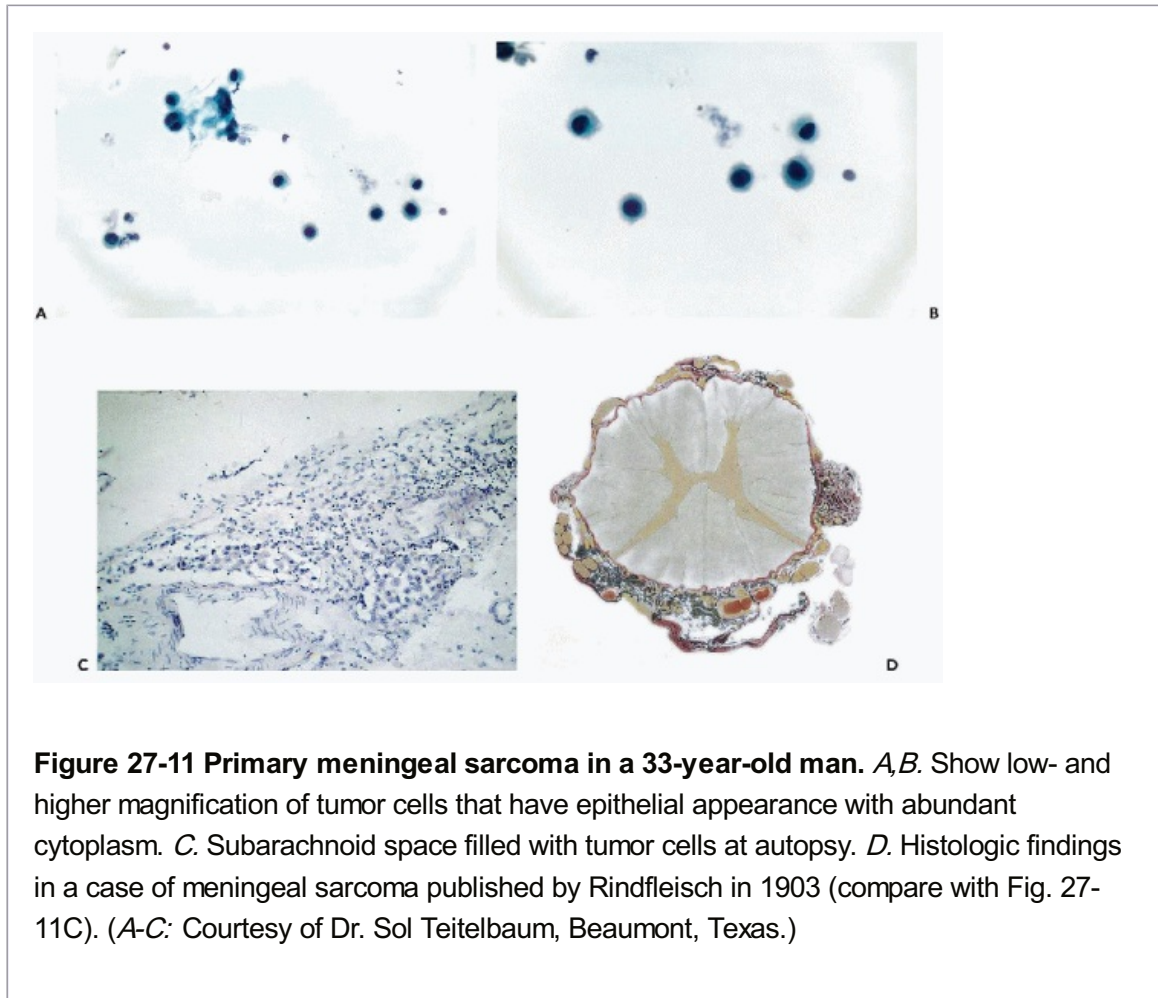

Meningiomas

These relatively common benign tumors of the meninges may be easily identified in needle aspiration biopsies, as discussed in Chapter 39. There is no record known to us of finding meningioma cells in CSF.

Primary Meningeal Sarcomas

These are **exceedingly rare tumors arising in leptomeninges**. The first published cases of this disorder were by Rindfleisch (1903) and by Dufour (1904), who was also **the first to describe cancer cells in CSF**. In a personally observed case, courtesy of Dr. Sol Teitelbaum, numerous **large malignant cells, singly and in clusters**, were seen in the CSF of a young man (Fig. 27-11A-C). Although the diagnosis of a malignant tumor involving the subarachnoid space was evident on cytologic material, the cells were thought to represent a metastatic carcinoma until a complete autopsy established the final diagnosis. There was a remarkable similarity between this case and the case described by Rindfleisch in 1903 (Fig. 27-11D). A nearly identical case was described by Garbos (1984). As these cases were seen before the onset of AIDS, the **possibility of a primary large cell lymphoma** was not considered in the

differential diagnosis and would be unlikely on review.

Primary Melanomas of Meninges

This is a rare disorder that may occasionally be diagnosed by cytology of the CSF before any space-occupying lesion is observed on a CT scan (Aichner and Schuler, 1982). Schmidt et al (1988) also described such a case and reviewed the literature, noting seven prior cases diagnosed by cytology of the CSF.

Cytology

The cytologic presentation may vary. In Aichner and Schuler's case, the **morphologic appearance of the cancer cells was inconspicuous and the melanin pigment was scanty**. The diagnosis was confirmed by ultrastructural studies that disclosed numerous melanosomes in tumor cells. In the case described by Schmidt et al, the **huge cancer cells** had abundant

P.1036

melanin pigment that obscured the cellular morphology; the diagnosis was confirmed on autopsy. **Metastatic melanoma**, particularly of **skin or occult ocular origin**, must be considered in the **differential diagnosis** of these rare cases (see below).

Leukemias

Next to the identification of infectious processes, discussed in the opening pages of this chapter, **the recognition of metastatic malignant tumors, particularly leukemias and**

lymphomas, is the most important task of cytologic assessment of the CSF. This has assumed an even greater significance because of the **epidemic of AIDS**, wherein the development of **lymphomas affecting the meninges or the brain** is a feared and common complication. Malignant lymphomas are also seen with increasing frequency **in organ transplant recipients**, with attendant immunosuppression; such tumors may arise in or involve the CNS (Witherspoon et al, 1989). Last, but not least, **leukemias, lymphomas, and some carcinomas**, particularly **bronchogenic carcinomas of small-cell type**, may be associated with **treatable occult cerebromeningeal metastases**. **Early recognition of these metastases by cytologic examination of CSF may be critical in deciding on further therapeutic measures that may significantly alter the course of the disease.**

The examination of CSF for the presence of **leukemic cells**, initiated by us around 1960, has become a routine procedure, especially in **the management of acute leukemia in children**. It has been shown that **leukemic cells may be present in CSF in asymptomatic patients with good response to therapy, before there are clinical manifestations of meningeal involvement**. Thus, CSF cytology serves to **monitor the effects of treatment** in sequential samples of CSF, **particularly in children** (Aronson et al, 1975; Mayer and Watson, 1980).

Another occult site of residual or recurrent leukemia in **boys is the testis**. In such cases, **prophylactic radiotherapy or chemotherapy to the brain and the meninges or testes has been shown to be an essential step in cure, which can now be achieved in a substantial proportion of young patients.**

Acute Lymphoblastic Leukemia

This is, by far, the most common form of leukemia in children that is usually of B-cell derivation. The air-dried blood smears or bone marrow smears, stained with Giemsa or another hematologic stain, have been the basis of a **morphologic classification** of acute lymphoblastic leukemias into **three groups**, L1, L2, and L3 (Zucker-Franklin et al, 1988). The cells in the L1 group are smaller than in the other two groups and usually show spherical nuclei with small indentations. Groups L2 and L3 are composed of larger cells. In group L2, the nuclei are irregular and show indentations and cleft formation. In group L3, the large nuclei have a smooth contour. Although this classification is no longer valid clinically, it is still of some value in morphologic recognition of leukemic cells (Harris et al, 2000; Jaffe et al, 2001). For reasons unknown, the **leukemic cells in CSF show a remarkable polymorphism, not observed in smears from the peripheral blood or bone marrow** (Kölmel, 1976).

At all times, **contamination of CSF by leukemic cells from peripheral blood may occur. Therefore, bloody taps should be considered with particular caution.** In blood-free CSF specimens, **a simple increase in the number of cells of the lymphocytic series in CSF**, under the appropriate clinical circumstances, **must be considered as a major warning** that a **lymphoblastic leukemia** may be present. This finding calls for a careful evaluation of the cytologic evidence. In **acute leukemias or in chronic leukemias in crisis**, **blast cells** in the CSF may be readily identified in fixed smears stained with Papanicolaou's method or one of the hematologic stains (Spriggs and Boddington, 1959; Rohlfing et al, 1981). In fixed material, the cells are recognized because of their **large size** (two to four times larger than normal lymphocytes), **a thin rim of delicate transparent cytoplasm**, and **two characteristic nuclear features: the presence of nuclear protrusions and of large nucleoli** (Fig. 27-12A). The protrusions vary in size and usually have the shape of a nipple. Although the nature of the protrusions is not clear, they have a **major diagnostic value**. Identical nuclear

protrusions may be observed in malignant lymphomas (see below) but they **are practically never observed in normal lymphocytes**. In air-dried material stained with Giemsa or another hematologic stain, the nuclear protrusions are obvious. Another cell feature that is not readily seen in fixed material is **hypersegmentation of nuclei**. In such cases, the nuclei are composed of multiple lobes of various sizes (Fig. 27-12B,C).

In fixed smears, the **nucleoli** appear as **pink nuclear inclusions**. In smears processed by hematologic techniques, the nucleoli appear as **“empty spaces” within the nucleus**. Aronson et al (1975) pointed out that cells with large nucleoli that could be classified as blast cells, but most likely represent immunoblasts, may also occur in the CSF in marked inflammatory lymphocytic reactions.

The Hand-Mirror Cells

Another feature that may be from time to time observed in leukemic cells is the **presence of hand-mirror cells, described as spherical cells with a cytoplasmic projection mimicking the “handle of a round mirror”** (see Fig. 27-14D). They were first observed in **lymphocytic leukemia** (Schumacher et al, 1977A), in **T-cell lymphoma** (Bernard et al, 1978) and **Burkitt's lymphoma** (Schumacher et al, 1978) but also occur in both **lymphoblastic and myeloblastic leukemias** (Schumacher et al, 1979, 1980; Cereso et al, 1984) and in **infectious mononucleosis** (Thomas et al, 1980). Zaharopoulos et al (1990) observed such cells **in the CSF** in leukemia, lymphoma, and in a **leukemoid reaction in a patient with AIDS**. Thus, the **specificity of the hand mirror cell as an expression of leukemia or lymphoma has not been proven**. In electron microscopy, Schumacher et al (1977B) and Zaharopoulos et al (1990) observed long cytoplasmic projections, accounting for the “handle” of these cells. It is thought that these cells represent some sort of immune response to unknown antigens.

Acute Myeloblastic Leukemia

Contrary to acute lymphocytic leukemia, which occurs mainly in children, the relatively uncommon acute myeloblastic

P.1037

leukemia occurs mainly in adults. In CSF stained with Papanicolaou, the morphologic picture is similar to that seen in acute lymphocytic leukemia (Fig. 27-12D). Hematologic stains and immunologic profile are needed to confirm the diagnosis.

Figure 27-12 Acute blastic leukemia. *A.* The appearance of cells in Pap-stained smear of CSF from a 7-year-old boy showing the irregular shape of leukemic cell nuclei with protrusions and folding. *B,C.* Air-dried Giemsa-stained smears of CSF at high magnification in an 11-year-old boy showing the bizarre configuration of the nuclei (see text). Large nucleoli appear as empty spaces. *D.* Acute myelogenous leukemia in a 70-year-old man. The leukemic nature of the disease is obvious but the type of leukemia could not be determined from this smear. (*B,C:* Courtesy of Dr. Eva Radel, Montefiore Medical Center.)

Chronic Lymphocytic Leukemia

The cytologic diagnosis is much **more difficult** in the rare instances of CSF involvement by **chronic lymphocytic leukemia (and corresponding small cell lymphomas)**. If the number of cells is large, the cell population is **monotonous** and composed exclusively of **small lymphocytes**. The diagnosis is fairly secure if the **nuclear chromatin of the lymphocytes is “lumpy” (cellules grumelées)** and the clinical data support the diagnosis. **If, however, the cell population is polymorphous**, the possibility of one of the **inflammatory or reactive meningitic processes**, described above, **must be considered**. It should be noted that **leukemias or lymphomas may be associated with a nonspecific meningeal reaction** because **the two disease processes are not mutually exclusive**. In such uncommon situations, the resolution rests on careful analysis of cytologic and clinical data that may require immunocytochemical and flow cytometric analysis.

Chronic Myelogenous Leukemia

Cerebrospinal fluid involvement in **chronic myelogenous leukemia** is very uncommon in my experience. When it does happen, the **cell population is heterogeneous**, with all stages of **granulocyte precursors** represented. The pattern **may be mistaken for a metastatic cancer**. The possibility of a **granulocytic sarcoma (chloroma)**, a **tumor-like manifestation of chronic myelogenous leukemia** with involvement of the brain or meninges, must be considered if a population of granulocyte precursors is observed in CSF in the absence of clinical leukemia. An example of this entity is shown in Figure 27-13. The case was characterized by numerous precursors of eosinophiles with formation of Charcot-Leyden

crystals. Lagrange et al (1992) described two patients in whom the first manifestation of chronic myelogenous leukemia was a granulocytic sarcoma.

Malignant Lymphoma

Non-Hodgkin's Lymphoma

Meningeal and cerebral involvement in non-Hodgkin's lymphomas is sufficiently frequent to warrant the examination of CSF as a **routine follow-up procedure** (Wiley, 1995). In most cases of small-cell lymphoma, the smear

P.1038

pattern in CSF is very similar to that described for acute lymphoblastic leukemia. The identification of malignant cells in CSF is similar to that described for effusions (see Chap. 26), with special emphasis on the presence of **nuclear protrusions and large nucleoli** (Figs. 27-14 and 27-15). Occasionally, a **“lumpy” chromatin pattern** may be observed (**cellules grumelées**, see above and Chap. 26). The **“hand-mirror cells”** were described above with acute leukemia (Fig. 27-14D). Such cells were observed in **T-cell lymphoma** (Bernard et al, 1978) and in **B-cell lymphoma** (Zaharopoulos et al, 1990).

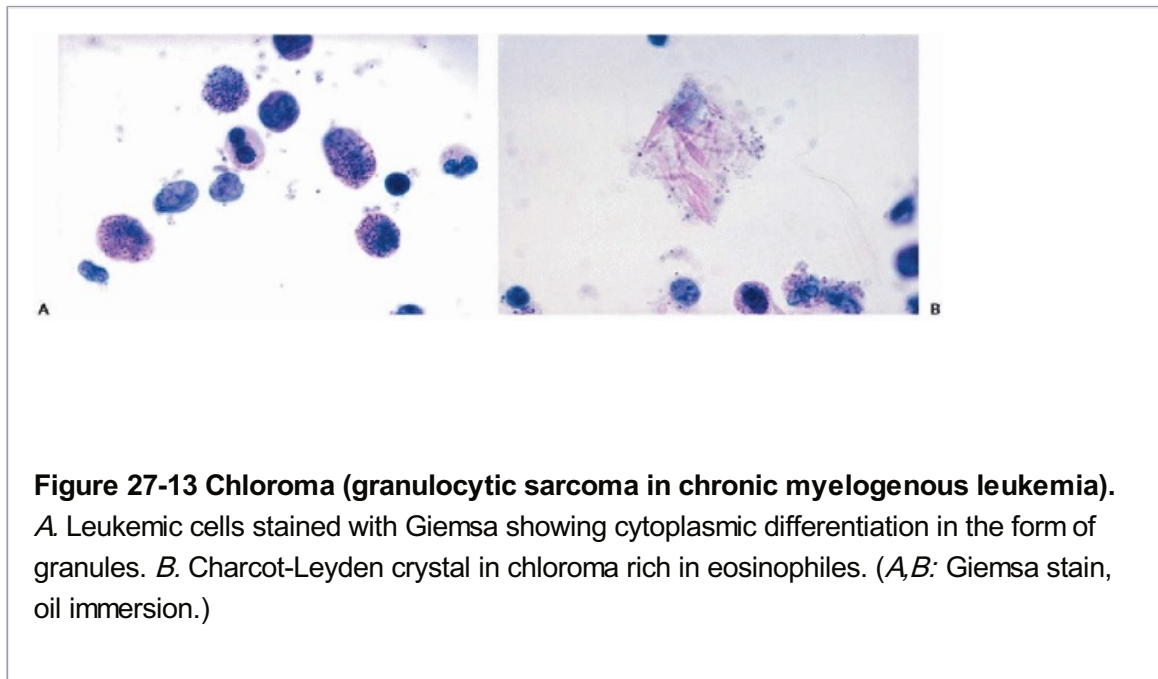

Figure 27-13 Chloroma (granulocytic sarcoma in chronic myelogenous leukemia).
A. Leukemic cells stained with Giemsa showing cytoplasmic differentiation in the form of granules. *B.* Charcot-Leyden crystal in chloroma rich in eosinophiles. (*A,B*: Giemsa stain, oil immersion.)

Figure 27-14 Malignant lymphoma in spinal fluid. *A.* Many large lymphoma cells that vary somewhat in size and show obvious nuclear abnormalities in the form of protrusions. *B.* Another example of malignant lymphoma showing variation in the size of the tumor cells, some of which contain large nucleoli. *C.* An example of large-cell malignant lymphoma showing prominent distortion of nuclear configuration. *D.* Malignant lymphoma cells, one of which shows a cytoplasmic extension, described as “hand mirror cells.” (*B-D*: High magnification.)

Cerebrospinal fluid can be used for **analysis and classification**

P.1039

of malignant lymphocytes by flow cytometry and immunocytopathology (see Case Report of the Massachusetts General Hospital, Case 39-1997). The fluid may also be used for other studies such as **scanning electron microscopy** (Domagala et al, 1977).

Figure 27-15 Metastatic malignant lymphoma to the meninges. *A,B.* Lymphoma cells

in CSF with mitotic activity and nuclear abnormalities described in text. Note “lumpy” chromatin pattern (“cellules grumelées”) in some cells at high magnification. *C.* A section of the original lymph node diagnosed as B-cell lymphoma in a 71-year-old woman. *D.* High magnification of cerebellum at autopsy shows deep infiltration of the subarachnoid space by lymphoma cells. The tumor produced numerous metastases to various organs, including the heart.

Malignant lymphoma, usually of the large-cell type, is a fairly frequent complication of **AIDS**, particularly in children, who nearly all die of it (Fig. 27-16A,B). The principles of cytologic diagnosis in CSF (and in effusions, for that matter, see Chap. 26) remain the same. On occasion, the **malignant lymphoma may be primary in the brain** (reviews in Bonnin, 1987; Hautzer et al, 1987) and the initial diagnosis may have to be rendered on CSF in the absence of peripheral disease. The presence of **herpesvirus type 8** may be valuable in **distinguishing a malignant lymphoma from a leukemoid reaction**. To establish the presence of **herpesvirus type 8** in AIDS patients, the CSF can be studied by PCR or by immunocytochemistry with a specific antibody (Dupin et al, 1999).

Rare Forms of Malignant Lymphoma

Malignant Histiocytosis (Histiocytic Medullary Reticulosis)

Most malignant tumors, previously classified as malignant histiocytosis, are now thought to be T-cell lymphomas. Still, there is a residue of this rare form of lymphoma, characterized by **erythrophagocytosis and a rapid, unfavorable clinical course**. A case of “**histiocytosis**,” primary in the **brain and meninges** in a young girl, was described by Wolfson (1979). **Large, abnormal cells with vacuolated cytoplasm were observed in the CSF**. Five cases of this type were described by Hamilton et al (1982). In four of them, erythrophagocytosis by abnormal histiocytes was observed in CSF. The question of precise classification of the diseases in this group of patients was discussed and the final diagnosis in some of them was insecure. A case of **metastatic malignant histiocytosis** with cancer cells in CSF was described by Carbone and Volpe (1980). Because these reports were published before antibodies to surface markers of lymphocytic cells became available, it is possible that the diagnoses would be modified today.

Multilobate Lymphoma

A case of **multilobate lymphoma** of the nasopharynx with a bizarre clinical course was observed by us (Fig. 27-16C,D). The multilobate cells in CSF contained **nuclear protrusions**, each provided with a **large nucleolus**. The patient died after intensive therapy and there was no residual evidence of disease at autopsy.

P.1040

Figure 27-16 Large cell lymphoma in AIDS (A,B) and lymphoma with convoluted nuclei (C,D). At high magnification, *A* shows the lymphoma cells with abundant cytoplasm and *B* shows the same cells stained with CD20, an antigen specific for B cells. *C,D*. Lymphoma with bizarre convoluted nuclei and mitotic activity in an elderly man. The nuclear cleaving was best seen with Giemsa stain in *D*.

Mycosis Fungoides

Cases of **mycosis fungoides** (T-cell lymphoma of the skin) with involvement of the CNS was described by Lundberg et al (1976) and by Bodenstein (1982). The characteristic **Sézary cells**, with **convoluted (cerebriform) nuclei**, were observed in CSF (see Chap. 34).

Plasmacytoma

The finding of a **few plasma cells** in CSF, as part of a heterogeneous population of inflammatory cells, is frequent in **chronic inflammatory processes**. If the plasma cells are the sole population of cells in CSF sediment, however, the diagnosis of **plasma cell myeloma** must be considered, even in the absence of cytologic abnormalities (Fig. 27-17). This may be a **direct extension of a vertebral or skull lesion** into the subarachnoid space or, very rarely, an **actual metastasis to the meninges**. Cavanna et al (1996) reported such a case with the presence of **lambda light chains** in the CSF and in urine. These authors also reviewed the literature on this topic and pointed out that some patients with plasma cells in CSF may have **plasma cell leukemia**. For further description and illustrations of cells of plasma cell myeloma in fluids, see Chapter 26.

Hodgkin's Disease and Lymphoid Granulomatosis

Involvement of the CNS and the meninges in Hodgkin's disease is **extraordinarily rare** and there is no known record of this disease diagnosed in CSF. **Lymphoid granulomatosis** is also a very rare malignant disorder that may affect the **brain** (and also the **lung and the upper respiratory tract**). This destructive disease may have a course similar to a malignant lymphoma and is associated with **Epstein-Barr virus** (summary in Guinee et al, 1995). It may be **mistaken for Hodgkin's disease** and is much more likely to shed cells into the CSF,

although there are no documented cases of this happening in the literature.

Sources of Error in Cytologic Diagnosis of Leukemia-Lymphoma in CSF

Borowitz et al (1981) discussed several pitfalls in the diagnosis of leukemia and lymphoma in CSF. Ten "false-positive" diagnoses were observed among 34 specimens diagnosed as "leukemia-lymphoma." Several sources of error were identified: **viral and fungal meningitis, viral encephalitis, contamination with peripheral blood** in cases of known leukemia, and a **postsurgical reaction**. Even though the authors attempted to identify the cytologic differences between the true-positive and false-positive cases, the evidence presented

P.1041

was not fully persuasive. Many of the "benign" cells illustrated had the characteristics of a malignant lymphoma with nuclear protrusions. The paper should serve as a warning that pitfalls may occur and great care is required for diagnosis. Several other observers (Rosenthal, 1984) also emphasized these sources of diagnostic errors. In our experience, the errors are avoidable if strict attention is paid to the morphologic presentation of cells in CSF, as described above. In cases of doubt, additional material should be requested and **processed by immunocytochemistry and flow cytometry**.

Figure 27-17 Multiple myeloma in CSF. A. A single plasma cell in CSF suggests multiple myeloma. Histologic section at autopsy (B).

CSF in Bone Marrow Transplantation

Bone marrow transplants, after suitable preparation to eradicate the residual malignant cells, are nearly routinely performed in patients with **leukemia**, less commonly with **malignant lymphomas**, and as an experimental procedure in **some solid tumors** such as carcinoma of the breast. The recipients of bone marrow transplantations are prone to a broad spectrum of infections (Fishman and Rubin, 1998) and the development of secondary cancers, mainly malignant lymphomas (Witherspoon et al, 1989). The cytology of the CSF in the transplant patients may serve two purposes:

- **To determine the presence of residual disease after transplantation**
- **To monitor patients for evidence of post-transplant infections or new malignant tumors**

CSF in bone marrow transplant patients, particularly in patients with leukemias and lymphomas, can be studied shortly after transplantation to determine whether any **residual**

cancer cells may be recognized. To our knowledge, there is only one systematic study of this problem. Lobenthal and Hajdu (1990) reviewed data on 1,049 CSFs from 265 bone marrow transplant patients, 127 of whom had leukemia. An increase in benign lymphocytes and macrophages was observed in 30%, and leukemia-lymphoma cells were identified in 17% of the patients. Contamination of the CSF with peripheral blood was one of the diagnostic problems. Another transplant-related disorder is the **severe chronic Epstein-Barr virus infection**, which may also result in significant and often fatal **lymphoproliferative disorders, associated with hemophagocytosis** (Ohshima et al, 1998).

Metastatic Carcinomas

Central nervous system involvement by metastatic carcinomas is an ominous event that was uniformly and rapidly fatal until the emergence of multidrug intensive chemotherapeutic regimens in the 1970s, with some unforeseen consequences. For example, a good response to chemotherapy of some small-cell cancers, such as oat cell carcinoma of the lung, **failed to prevent cerebral and meningeal involvement** (Aisner et al, 1979). In other words, these tumors, previously virtually incurable, now may respond to treatment but behave in a fashion **similar to leukemias or malignant lymphomas**, described above. For some other carcinomas, such as **mammary carcinomas**, new therapeutic options also altered the short-term prognosis. Although cure of these cancers after involvement of the CNS is still impossible, short remissions with a good quality of life can now occur. **Consequently, the identification of cells of metastatic carcinoma has acquired, in some cases, new significance beyond diagnosis, as it may lead to aggressive, life-prolonging or life-saving therapy.**

The **cytologic presentation** of metastatic cancer in CSF depends on the **type and site of metastases and type of tumor**. Single, focal metastases usually shed a limited number of cancer cells, singly or in clusters. **Massive cytologic evidence of cancer usually indicates meningeal carcinomatosis, a diffuse involvement of the subarachnoid space.** Still, in our experience, the recognition of the organ of origin, or even tumor type, may be extremely difficult in cytologic preparations in the absence of clinical history.

Cancer cells may be **accompanied by reactive lymphocytosis and by macrophages**. As a general rule, **cells of metastatic carcinomas, even of small size, are larger than transformed lymphocytes**. In general, the **recognition of metastatic carcinoma in CSF is comparatively easy in good preparations.**

The most commonly identified metastatic carcinomas in CSF from women are of **mammary origin and, in men, of**

P.1042

bronchogenic origin. The cytologic presentation of tumor cells in CSF is similar to that observed in effusions and described in detail in Chapter 26.

Mammary Carcinoma

Small-cell carcinomas, usually of lobular type, shed scattered **small cancer cells, sometimes of signet ring-type configuration** and a central condensation of mucus within the cytoplasmic vacuole ("target cell," see Chaps. 26 and 29). Occasionally, **chains of cancer cells** are noted. Although this cell arrangement is **not specific** for mammary carcinoma, as it may also be observed in other tumors, it should suggest mammary carcinoma in an appropriate clinical setting.

The **ductal type of mammary carcinoma** sheds large, readily recognizable cancer cells that

may sometimes show **peripheral cytoplasmic blobs** or protrusions. Microvilli may be observed, particularly in air-dried preparations (Fig. 27-18). In other cases, cancer cells with large nuclei and nucleoli may be recognized. Mitotic figures may occur.

Bronchogenic Carcinoma

In general, the cytologic presentation of lung cancer in CSF follows the pattern seen in effusions. **Squamous or large-cell undifferentiated carcinomas** shed **large, sometimes huge, cancer cells** often in small clusters (Fig. 27-19A,B). **Adenocarcinomas** also shed large cancer cells, usually with large nucleoli. Other bronchogenic carcinomas usually shed smaller cancer cells, sometimes with cytoplasmic vacuoles. There are sometimes significant differences in cancer cell sizes between the primary and metastatic tumors (Fig. 27-19C,D). **Oat cell carcinoma** sheds **small cancer cells**, often singly and also in clusters, and **sometimes arranged in short chains with nuclear molding** resembling a string of vertebrae (see Chap. 26). Ringenberget al (1990) reported on three patients with positive CSF and unknown primary, subsequently documented to be of lung origin.

Figure 27-18 Metastatic carcinoma of breast in CSF. *A.* Large malignant cells with abundant cytoplasm, occurring singly and in clusters. *B.* Large cancer cells showing prominent nucleoli and mitotic activity. *C.* Primary mammary duct carcinoma corresponding to *B.* *D.* Metastatic mammary cancer cells in CSF showing cytoplasmic blebs and protrusions.

Other Carcinomas

Carcinomas of **virtually every origin** may occasionally metastasize to the CNS and be recognized as cancers in CSF. Thus, **bladder and prostate cancer** are seen with fair frequency (Eyha et al, 1981). Stastny et al (1996) described the presence of “caudate” cells (later renamed “cercariform” cells) in a metastatic urothelial carcinoma (see Chaps. 23 and 26). We have also observed metastatic **pancreatic, gastric, thyroid** and other carcinomas in CSF. A case of squamous carcinoma of the cervix recognized in CSF is shown in Figure 27-20. The tumor formed a cyst-like metastasis in the spinal cord and the smear contained mainly necrotic

squamous cells with only an occasional well-preserved cancer cell. Another case of squamous carcinoma of the cervix in CSF was described by Weithman et al (1987).

Figure 27-19 Metastatic lung cancer in CSF. *A,B.* Show very large cancer cells with abundant cytoplasm. The primary tumor was a poorly differentiated squamous carcinoma. *C.* Bronchial brush specimen showing a poorly differentiated lung cancer, corresponding to much smaller cells of the same tumor in spinal fluid, shown in *D.*

Metastatic Malignant Melanoma

Of special interest in adults is **metastatic melanoma**, which may affect the central nervous system as the only metastatic site, **sometimes many years after removal of the primary tumor**. The malignant cells are often **numerous**, indicating **massive meningeal involvement**, are often remarkably well preserved and, in nearly all such cases, have an epithelial configuration (Fig. 27-21A,B). In the absence of pigment formation, the exact identification of tumor type may prove difficult, particularly if a history of the primary tumor is remote and forgotten or unknown (Fig. 27-21C,D). Rarely,

abundant pigment may obscure the morphologic details of cells. As has been said in reference to other sites of metastatic malignant melanoma, **the search for cells with morphologic features of a malignant tumor is mandatory in such cases to ascertain that the underlying lesion is a melanoma and not melanosis**. For further detailed analysis of cells of metastatic malignant melanoma and their recognition in fluids, see Chapter 26.

Figure 27-20 Smears from spinal fluid containing squamous debris and isolated squamous cancer cells from a metastatic cystic squamous carcinoma of the uterine cervix.

Figure 27-21 Malignant melanoma in spinal fluid. *A.* A large cluster of epithelial-type cancer cells with spotty brown granular pigment in the cytoplasm. *B.* High magnification of the pigmented cancer cells. *C.* Another example of metastatic malignant melanoma to CSF showing epithelial type cancer cells without pigment formation. *D.* The lymph node containing metastatic malignant melanoma, corresponding to cells shown in *C.*

Chordoma

These tumors of the **notochord** usually occur at the two extremities of the spinal column, **either at the cranial end or near the sacrum** (review in Rich et al, 1985). In fortuitous and extremely rare cases, the characteristic **physalipherous cells**, provided with a large, vacuolated, “bubbly” cytoplasm and a peripheral, spherical nucleus, may be recognized in spinal fluid. Sometimes the tumor cells closely mimic cartilage cells. Similar cells, however, may be derived from an inadvertently aspirated **nucleus pulposus**, the central portion of a herniated intervertebral cartilage (see Fig. 27-1C). Ali et al (1995) observed physalipherous

cells in the CSF of a 2-year-old girl with chordoma of the cervical spine. For further discussion of cytologic presentation of chordomas in aspiration biopsies (FNA), see Chapter 36.

Childhood Tumors

Besides **leukemias and rare malignant lymphomas, neuroblastomas** were seen with a fair frequency before introduction of contemporary therapy (see Fig. 27-9A). Contrary to the presentation in aspiration biopsies and sometimes in effusion, **rosettes were virtually never observed in the CSF** and only single cancer cells, sometimes with cytoplasmic filaments, were noted. Silverman et al (1992) presented a good summary of **differences between neuroblastomas and the rare primitive neuroectodermal tumors**. The latter have not been reported in CSF.

We observed a case of **embryonal rhabdomyosarcoma of the inner ear** with metastases to the spinal cord and cancer cells in the CSF in a 4-year-old child. **Small cancer cells** with relatively **abundant eosinophilic cytoplasm** were noted but, in the absence of cytoplasmic striations, a diagnosis of tumor type could not be established in the fluid (Fig. 27-22).

Spinal Fluid in Assessment of Effect of Treatment

Samples of spinal fluid, repeatedly obtained from patients under treatment for metastatic involvement of the meninges

P.1045

or the CNS, may yield information on the response of the tumor to therapy. The **effects of therapy on the CSF cytology in acute leukemia** have been studied by Aaronson et al (1975). It was shown that, with the onset of therapy, there is a **rapid and marked reduction of blast cells, leading to their complete disappearance**. Also, in **leukemias and malignant lymphomas, apoptosis (karyorrhexis)** of tumor cell nuclei has been observed by us during and after treatment.

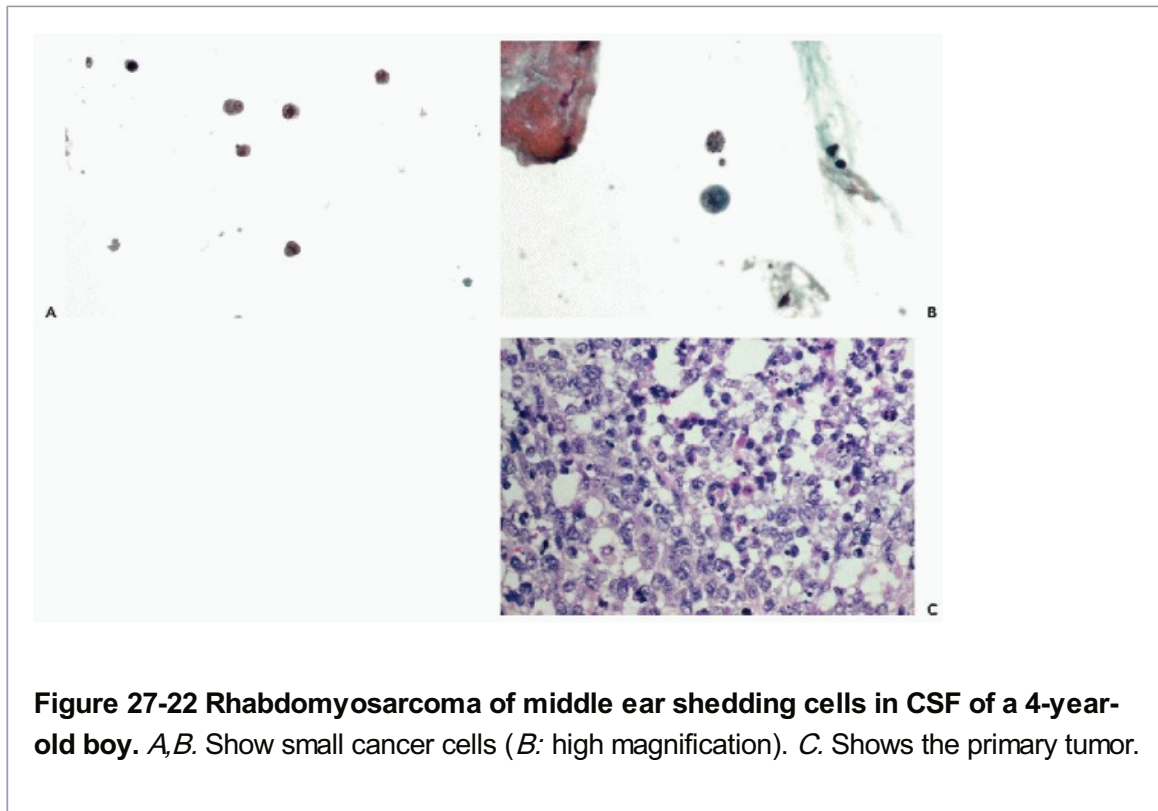

Figure 27-22 Rhabdomyosarcoma of middle ear shedding cells in CSF of a 4-year-old boy. A,B. Show small cancer cells (B: high magnification). C. Shows the primary tumor.

In **epithelial tumors**, cell changes, mainly **enlargement and vacuolization of the nucleus and cytoplasm**, may be brought about by radiotherapy or chemotherapy. We have observed such changes in cells of mammary carcinoma, treated with intrathecal methotrexate. Except for the investigation by Aaronson, cited above, there has been no systematic investigation of these changes and the observations are anecdotal.

MISCELLANEOUS FLUIDS

SYNOVIAL FLUID

Normal Synovial Fluid

Viscous synovial fluid, which lubricates the joints, is secreted by **synovium, a membrane lining the joint capsules, provided with a highly specialized epithelium**. Under normal circumstances, the fluid forms a thin layer moistening the surface of the joints. Normal synovial fluid is, therefore, very rarely studied. In fortuitous cases, the fluid is essentially **acellular**, except for a **few synovial lining cells** that resemble **small mesothelial cells** (see Chap. 25) and debris, possibly representing fragments of cartilage. The volume of synovial fluid may **increase** after **trauma** or **inflammation** and can then be aspirated for cytologic analysis.

Cytology in Nonmalignant Disorders

Ganglion Cysts

Ganglion cysts are a common benign disorder of synovial membranes, observed clinically as a **smooth subcutaneous swelling that fluctuates on pressure**. The cysts are usually located at the level of a joint or a bursa. The diagnosis of a ganglion cyst is usually established clinically and aspiration of the fluid is usually performed for therapeutic rather than diagnostic purposes. Dodd and Layfield (1996) observed that the aspirated fluid was **thick and gelatinous**. Cytologic examination revealed **rare macrophages embedded in a gelatinous matrix**. Perhaps the most important role of cytologic examination is to rule out the rare neoplastic lesions mimicking ganglion cysts.

Inflammatory Disorders

During the **acute stage of inflammatory disorders** (acute arthritis caused by trauma or by bacterial infection), the

P.1046

number of cells in synovial fluid is greatly increased, the majority being **polymorphonuclear leukocytes**. Naib (1973) pointed out that in **traumatic arthritis, degenerated cartilage cells** may be observed singly and in sheets. **Cartilage cells and fragments** may also be present in **degenerative joint diseases (osteoarthritis)** of various etiologies.

Acute arthritis may also occur as a complication of **gonorrhea** and other incidental bacterial infections caused by organisms such as streptococci and staphylococci. **Reiter's syndrome**, which causes acute arthritis and inflammation of the **conjunctiva and urethra**, is caused by an infection with *Chlamydia* species that may be recognized as tiny intracytoplasmic inclusions in synovial cells (Naib, 1973). For a detailed discussion of chlamydial agents, see Chapter 10.

In **chronic inflammatory disorders**, the synovial fluid greatly resembles other benign effusions: **synovial (mesothelial) cells, leukocytes, and macrophages** are evident.

Villonodular Synovitis and Giant Cell Tumors of Tendons

Villonodular synovitis is a chronic inflammatory condition in which there is a **thickening of the synovial membrane**, associated with **papillary proliferation of synovial cells**, macrophages containing **brown hemosiderin pigment**, and **multinucleated giant cells**. The affected joint is usually swollen with **accumulation of synovial fluid**. The condition may occur in any joint, even the temporomandibular joint, as in a case reported by Yu et al (1997) and it may be recognized in synovial fluid.

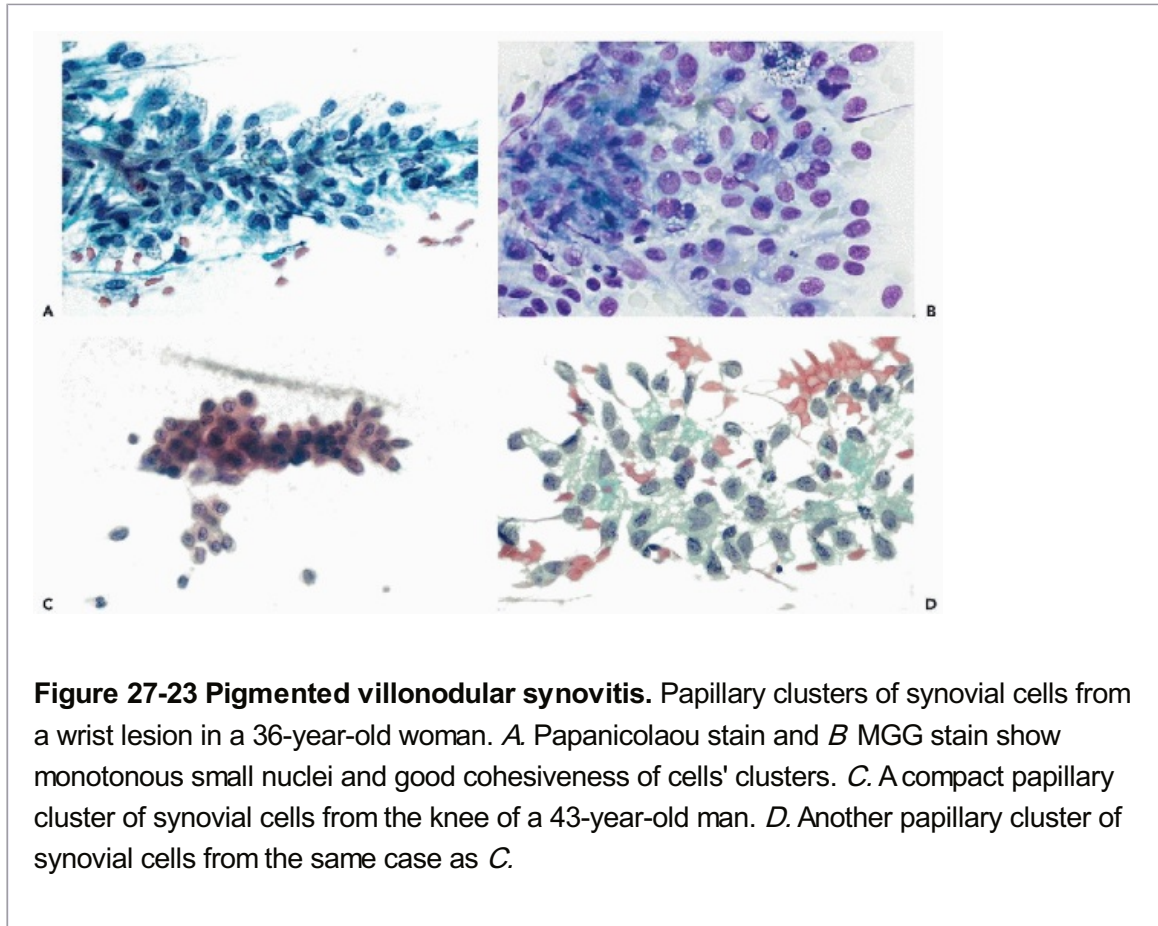

Figure 27-23 Pigmented villonodular synovitis. Papillary clusters of synovial cells from a wrist lesion in a 36-year-old woman. *A*. Papanicolaou stain and *B* MGG stain show monotonous small nuclei and good cohesiveness of cells' clusters. *C*. A compact papillary cluster of synovial cells from the knee of a 43-year-old man. *D*. Another papillary cluster of synovial cells from the same case as *C*.

Structurally similar lesions may occur in bursae and tendon sheets and may be diagnosed by fine-needle aspiration biopsy (FNA) (Agarwal et al, 1997; Layfield et al, 1997; Shapiro et al, 2002).

Smears of synovial fluid reflect the histologic findings. Sheets of synovial cells, sometimes forming papillary clusters, may be the best evidence of this disorder (Fig. 27-23). Polygonal **large epithelial cells** of various shapes and **macrophages**, usually containing **brown cytoplasmic granules of hemosiderin**, are observed next to **scattered multinucleated giant cells of osteoclastic type** that may contain up to 50 nuclei. The **nuclei of the giant cells** are **dispersed throughout the cytoplasm, vary somewhat in size, and may contain visible nucleoli** (Fig. 27-24). Some of the giant cells resemble the so-called **Touton giant cells**, in which the nuclei show a **wreath-like peripheral arrangement**. Similar cytologic observations were

P.1047

reported by Chhieng et al (1997). This type of giant cells may also be observed in **other forms of chronic synovitis** and in **giant cell tumors of bone** involving joints (see below).

Figure 27-24 Pigmented villonodular synovitis from the middle finger of a 34-year-old woman. *A.* Shows a large, compact cluster of synovial cells and a multinucleated giant cell of osteoclastic type. *B.* Dispersed synovial cells showing abundant cytoplasm and peripheral nuclei with prominent nucleoli. The background shows inflammatory cells. *C.* Two multinucleated giant cells accompanied by dispersed synovial cells. *D.* Histologic section of the lesion showing proliferation of synovial cells with several dispersed multinucleated giant cells. (Case courtesy Dr. Jacek Sygut, Kielce, Poland.)

Nearly identical cytologic abnormalities are observed in FNAs of the **extraarticular tenosynovial giant cell tumor of soft tissues**, either located in the immediate vicinity of joints or elsewhere (González-Cámpora et al, 1995; Layfield et al, 1997). This tumor may also show **cytogenetic abnormalities** affecting chromosomes 1 and 2 that may also be found in villonodular synovitis (summary in González-Cámpora et al, 1995).

Another important point of differential diagnosis is formation of the **callus after fracture of bone** adjacent to the joint. In aspirates of joint fluid, **large multinucleated giant cells (osteoclasts)** may be evident mimicking villous synovitis (Fig. 27-25). **Megakaryocytes** may also be sometimes inadvertently aspirated from adjacent bone marrow by an inexperienced person.

Rheumatoid Arthritis

This chronic disease, presumed to be of immunologic etiology, may affect patients of all ages, and it is usually diagnosed by clinical and laboratory data rather than cytology. **Progressive deformity and painful swelling of joints** is the hallmark of the disorder. Formation of classical **rheumatoid nodules** in the soft tissues surrounding the joints, or in internal organs, was discussed in Chapter 25.

Synovial fluid in rheumatoid arthritis has been studied, notably by Hollander et al (1966). The fluid, which is usually sticky and may coagulate on standing, shows evidence of acute and chronic inflammation and sometimes scattered **fragments of cartilage and chondrocytes**. Of special note is the presence of **neutrophilic polymorphonuclear leukocytes containing in their cytoplasm from 2 to 15 dark, basophilic, round inclusions** (Fig. 27-26). Hollander

named these cells R(heumatoid) A(rthritis) cells, whereas Delbarre (1964) named such cells **ragocytes**, and this name has been generally accepted. It has been postulated that the inclusions represent an accumulation of immunoglobulins (Fallet, 1968). Naib (1973) has observed such cells in other disorders affecting joints, for example in **rheumatic arthritis**, and considered ragocytes **as specific for rheumatoid arthritis, only if found in excess of 10% of the cell population in the synovial fluid**.

P.1048

Figure 27-25 A callus imitating villonodular synovitis. *A.* A multinucleated giant cell of osteoclastic type. *B.* Corresponding tissue section showing proliferation of fibroblast and multinucleated giant cells in a callus of ribs.

Disseminated Lupus Erythematosus

Lupus erythematosus (LE) cells can be observed in joint fluid accompanying this disease. For a detailed description of these cells, see Chapter 25.

Gout and Pseudogout

Gout is a chronic and painful inflammation of joints caused by **faulty metabolism of urates**, affecting mainly the great toe but also other joints, and even the temporomandibular joint. Naib (1973), Suprun and Mansoor (1973), Liu et al (1996), and Nicol (1997) reported the presence of **uric acid crystals** in synovial fluids. The **birefringent** crystals are **needle-shaped** and either lie freely in fluid or are phagocytosed by polymorphonuclear leukocytes. The crystals are **diagnostic of gout**. They can be observed in fluids aspirated from various joints. Larger deposits of uric acid crystals form palpable nodules or tophi. Figure 27-27 shows a fragment of a tophus aspirated from a toe mass in a patient with gout.

Figure 27-26 Ragocytes in smear and cell block. Note neutrophilic polymorphonuclear leukocytes containing dark basophilic inclusions in their cytoplasm. (Photographs courtesy of Dr. Bernard Naylor, Ann Arbor, Mich.)

Pseudogout is an inflammatory, often hereditary, joint disease, caused by deposition of **calcium salt crystals**. Zaharopoulos and Wong (1980) observed calcium pyrophosphate crystals in fresh joint fluids, in the form of **rod-shaped or rhomboid structures**.

Other Inorganic Material and Crystals in Synovial Fluids

In various forms of arthritis, **noncrystalline deposits of calcium** were occasionally noted. Other crystals, such as the flat, rhomboid, "broken glass" **cholesterol crystals**, can occasionally be observed (Naib, 1973). Naib also reported **talcum crystals** observed in synovial fluid after surgical repair.

Malignant Tumors in Synovial Fluid

For a successful diagnosis of a malignant tumor in synovial fluid, the tumor either has to **originate in the joint or invade the joint from adjacent bone**, leading to an accumulation

P.1049

of synovial fluid as the first evidence of disease. These events are uncommon and the recorded cases are very few. Meisels and Berebichez (1961) reported three cases of **osteogenic sarcoma** diagnosed on synovial fluid, two from the lower extremities and one from the shoulder. The cytologic findings were those of malignant tumors but the specific features of this tumor, that is, formation of primitive bone, were not recorded. We have also observed one such case in a joint fluid aspirated from the knee of a 12-year-old boy. The diagnosis of a malignant tumor could be established on the smear whereas the cell block contained a fragment of osteoid-forming tumor (Fig. 27-28A,B). Naib (1973) reported two cases of **synovial sarcoma**, described as **malignant cells of epithelial type**. The **biphasic nature** of the tumor was not reported. We observed a case of a **recurrent giant cell tumor of bone** in synovial fluid, characterized by numerous **multinucleated osteoclast-like giant cells**, shown in Figure 27-28C. For a detailed description of cytology of these tumors, see Chapter 36.

Figure 27-27 A tophus of toe. Inadvertently aspirated tophus consisting of innumerable needle shape crystals of uric acid in a patient with gout. A few inflammatory cells are attached to the periphery of the tophus.

Figure 27-28 Bone tumors in synovial fluid. A,B. Show osteogenic sarcoma in a smear (A) and cell block (B). Scattered highly malignant cells are present in this smear. Formation of osteoid is seen in the cell block. C. Giant cell tumor of bone. Several multinucleated giant cells and scattered stromal cells may be observed.

Metastases to joints are also rare and only a few such cases have been reported. Naib reported four **metastatic tumors** recognized in synovial fluid, one from a prostatic carcinoma. The cytologic findings were those of a malignant tumor but were not specific for tumor type. Thompson (1996) also reported two such cases, one an oat cell carcinoma of lung origin and

one of non-Hodgkin's lymphoma. We have observed a case of pulmonary adenocarcinoma in knee joint fluid. Although the tumor type was not evident in the smear, the cell block contained fragments of adenocarcinoma.

HYDROCELE FLUID

Aspiration of fluids accumulating in the mesothelial sac, **or the tunica vaginalis of the testes (a hydrocele)**, is a common procedure. Usually the fluids are clear and nearly acellular, but occasionally, markedly **atypical mesothelial cells**

P.1050

with enlarged and markedly hyperchromatic nuclei, singly and in sheets, may be observed therein (Fig. 27-29). These cells, which **mimic malignant cells to perfection**, are an important source of **diagnostic error**. Similar observations were reported by Pisciolli et al (1983) and by Stephen et al (1999).

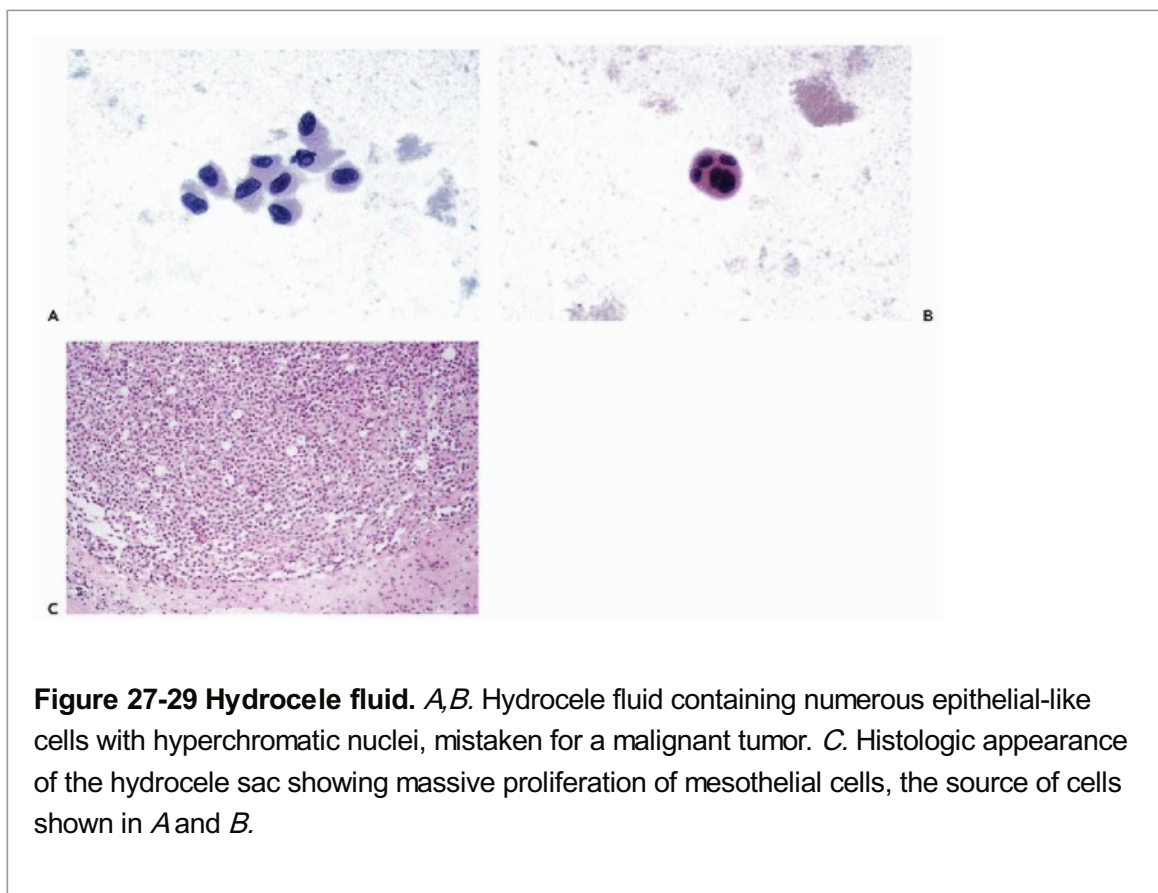

Figure 27-29 Hydrocele fluid. *A,B.* Hydrocele fluid containing numerous epithelial-like cells with hyperchromatic nuclei, mistaken for a malignant tumor. *C.* Histologic appearance of the hydrocele sac showing massive proliferation of mesothelial cells, the source of cells shown in *A* and *B*.

Malignant Tumors

Rare **primary mesotheliomas** have been observed in **tunica vaginalis testis** and in **hernia sacs** (Tang et al, 1976). A case of primary malignant mesothelioma of the tunica vaginalis testis, identified in hydrocele fluid, is described and illustrated in Chapter 26. **Because benign nodular proliferation of mesothelial lining may also occur and may shed atypical mesothelial cells**, the differential diagnosis between benign and malignant mesothelial proliferation may be difficult and is discussed in Chapter 26.

Occasionally, a **malignant testicular tumor, usually a seminoma, may be observed in hydrocele fluid**. For discussion of cytologic presentation of seminomas, see Chapter 33. An extremely rare malignant tumor is the **melanotic neuroectodermal tumor of infancy** (previously known as a **retinal anlage tumor** [Kapadia et al, 1993]). The tumor mimics

embryonal eye formation and contains **pigmented (retinal) cells**. Toda et al (1998) described the cytology of one such tumor located in the **epididymis** of a 5-year-old infant. Small and large melanin-containing cancer cells were described. The cytology of **nonmelanotic primitive neuroectodermal tumors** in other locations was discussed by Silverman et al (1992).

AMNIOTIC FLUID

Amniocentesis, or aspiration of amniotic fluid, usually past the 16th week of pregnancy, is performed under ultrasound guidance for the identification of **congenital abnormalities** in the fetus and for the **determination of fetal sex**.

Cytology of Normal Amniotic Fluid

Although the principal tool in the study of amniotic fluid is a **cytogenetic analysis**, the morphology of the cells in the fluid is occasionally of interest. A detailed analysis of the cells found in amniotic fluid with histologic correlation has been reported by Casadei et al (1973), Morris and Bennett (1974), Schnage et al (1982), Blekinsopp et al (1984), and Greenebaum et al (1997).

The **cells of fetal origin** are:

- **Anucleated squames of buccal or skin origin**
- **Nucleated squamous cells of superficial and intermediate type, of skin, vaginal, and buccal origin**
- **Epithelial cells derived from the urinary tract**
- **Nucleated cells of parabasal type, probably of amniotic origin**

P.1051

- **Amnion cells, occurring singly or in sheets and clusters**
- **Fragments of chorionic villi**
- **Macrophages**

Blekinsopp et al (1984) analyzed the proportion of various cell components in amniotic fluid from 480 patients who were 16 to 20 weeks pregnant. Actual cell counts were performed in cytocentrifuge preparations of 50 normal fluids. **Squamous cells of superficial and intermediate type formed 80% of the cell population** in the samples. The recognition of these cells presented no difficulties, as their morphology was identical with similar cells of female genital tract or respiratory tract origin. Schrage et al (1982) also identified **superficial urothelial "umbrella" cells in amniotic fluid** (see Chap. 22).

Amnion cells, singly and in sheets, constituted 12% of the cell population. The cells were about the size of small parabasal squamous cells, with central small nuclei, and were distinguished by **marked peripheral thickening of the cytoplasm**. Occasionally, the nuclei of the amnion cells were peripheral.

Small **macrophages**, always occurring singly, formed about **2% of the cell population**. The cells had **vacuolated cytoplasm**. Some of the macrophages had an **elongated cytoplasmic tail** and were thought to represent cells known as **Hofbauer cells of the placenta**.

The remainder of the cell population was represented mainly by **nucleated fetal**

erythrocytes, somewhat larger than mature erythrocytes. **Small lymphocytes and neutrophils** were observed.

The placenta was represented by **tips of chorionic villi, seen as cohesive clusters of small, tightly bound cells**, usually with sharply demarcated clear cytoplasmic borders, that constituted **16%** of the normal specimens. Placental **cytotrophoblasts** were identified as small, usually cuboidal basophilic cells, with somewhat hyperchromatic nuclei with a coarse chromatin pattern. **Syncytiotrophoblasts** were observed as large multinucleated cells.

Determination of Fetal Sex

Next to chromosomal karyotyping, the most reliable methods for determination of fetal sex are the **count of sex chromatin bodies and identification of Y chromosomes in squamous cells**. In **female fetuses**, the sex chromatin bodies are usually found in **20% or more of squamous cells**. It is of interest that a **low percentage of cells with sex chromatin bodies (up to 4%) may be observed in male fetuses**, probably because of **contamination with maternal cells**. The identification of the male Y chromosome by quinacrine fluorescence or fluorescent in situ hybridization are very reliable. Errors are very few and usually pertain to a very small Y chromosome or a laboratory error (Adams et al, 1973). Since the size of the Y chromosome is an inherited characteristic, Adams et al (1973) recommends a **simultaneous examination of the father's Y chromosome to determine its size**.

Other methods of sex determination, based on counts of cyanophilic squamous cells, or the determination of the karyopyknotic index in amniotic fluids stained with Papanicolaou method (Arendzen and Huisjes, 1971; Hudson, 1975), are no longer used.

Estimation of Gestational Age

The estimation of **lipid-containing cells stained with Nile blue sulfate** as an **index of fetal maturity** was discussed by Johannsen (1974). This paper contains a summary of reported data and records an accuracy of plus or minus 1 week in 72% of 106 women studied. The method is cited for historical reasons, as the gestational age can now be determined with great accuracy by ultrasound examination.

Estimation of Fetal Death

Amniotic fluid containing **necrotic cells, ciliated cells of respiratory tract origin, bacteria, fungi, or intranuclear inclusions, consistent with a herpesvirus infection, are strongly suggestive of fetal death in utero**.

Identification of Congenital Abnormalities

The principal reason for transabdominal sampling of amniotic fluid, or **amniocentesis**, that can be performed in the 16th week of pregnancy, or the **sampling of chorionic villi** that can be performed after 8 weeks of pregnancy, is the recognition of congenital abnormalities. One of these procedures should be performed on women with a **high risk for an abnormal pregnancy** because of age or other factors. **Cytogenetic techniques**, performed in licensed and appropriately supervised laboratories, offer nearly foolproof evidence of almost all major chromosomal disorders.

Processing of Amniotic Fluid

In the state of New York, each cytogenetic examination must be performed twice, on two

samples of the same fluid, to ensure the highest possible level of accuracy. The cells from the amniotic fluid are cultured in two separate incubators, treated with colchicine to arrest mitotic division in the metaphase stage, and the chromosomes analyzed for number and morphology, using the Giemsa (G)-banding technique. The most commonly encountered karyotypic abnormality is **Down's syndrome (trisomy 21)** with other abnormalities being much less frequent (for further discussions, see Chap. 4).

Chorionic Villi Sampling

In skilled hands, amniocentesis may be replaced by a cytogenetic analysis of tissue obtained by a direct biopsy of placental chorionic villi, preferably under ultrasound guidance (Horwell et al, 1983; Simoni et al, 1983). There is one clear **advantage to this method: the analysis may be performed from the 8th week of pregnancy on**, when a termination of pregnancy, if desired, is much easier than after the 16th week of pregnancy, required for amniocentesis. The tissue is processed in a fashion similar to the amniotic fluid. The **disadvantage** of the method is the **difficulty with obtaining**

P.1052

adequate chromosomal spreads. The chromosomes tend to be “fuzzy” and the cytogenetic analysis is more difficult than in amniotic fluids. A short-term culture of the trophoblastic tissue improves the quality of the preparations. The fetal wastage (induced abortions) is about 1% of pregnancies, apparently somewhat higher than for amniocentesis (Rhoads et al, 1989; Doran, 1990).

Neural Tube Closure Defects

Neural tube closure defects may result in a broad range of congenital abnormalities, ranging from **anencephaly**, which is not compatible with survival, to **spina bifida**. The recognition of these abnormalities is based on ultrasound examination of the fetus, supported by elevation of **alpha-fetoprotein levels in the amniotic fluid**. However, before this technology was perfected, a **cytologic analysis of the amniotic fluid was diagnostic of anencephaly, with a high level of accuracy** in experienced hands (Chapman et al, 1981; Blenkinsopp et al, 1984). Lesser degrees of neural tube closure defect, such as spina bifida, could not be identified by cytologic methods.

Anencephaly was characterized by the presence of numerous **primitive neural cells and large, pigmented, lipin-laden macrophages**. The **neural cells were small, about 5 to 6 μm in diameter**, with barely visible cytoplasm and densely staining nuclei. The cells occurred **singly** and in **loosely structured clusters**, some of which, in the view of this writer, **resembled rosettes seen in neuroblastomas**. An excellent correlation of these cells with cells present in histologic material on the surface of the neural defect was illustrated (Blenkinsopp et al, 1984). The method may still prove to be of diagnostic value in the absence of suitable ultrasound equipment. Greenebaum et al (1997) confirmed by immunocytochemistry that the small cells were of neural origin.

Molecular Biologic Techniques

Prenatal screening may be performed to detect **genetic abnormalities** associated with several congenital disorders. Thus, **mucoviscidosis (cystic fibrosis)**, **Huntington's disease**, and several other inheritable abnormalities may be discovered, some of which may be amenable to treatment. The description of these observations is beyond the scope of this book and the reader is referred to other sources.

Amniotic Fluid Embolism

Amniotic fluid embolism is an often **fatal complication of childbirth**, caused by the transfer of amniotic fluid to maternal circulation, with resulting **embolization of the lung by fetal squamous cells**. Botero and Holmquist (1979) were the first to describe finding **fetal anucleated squamous cells in a blood sample** obtained through a Swan-Ganz catheter **from the right heart of a patient** with amniotic fluid embolism. Several similar case reports have appeared in the literature (summary in Lee et al, 1986). Of note was the use of an **antibody to human keratin** that facilitated the recognition of squamous cells (Garland and Thompson, 1983). Clearly, the use of **monoclonal antibodies to keratin filaments** would be equally useful.

Other Fluids

From time to time, other body fluids are examined cytologically. As an example, Tanaka et al (1985) reported on **washings of a maxillary sinus** in a case of **carcinoma associated with aspergillosis**.

Techniques of Fine-Needle Aspiration, Smear Preparation, and Principles of Interpretation

Britt-Marie Ljung

P.1057

Although most cytopathologists and clinicians who use fine-needle aspiration (FNA) biopsy in their practices are aware of the relationship between expertise in microscopic interpretation and diagnostic accuracy, the importance of sample quality and smear preparation is less well recognized. Several studies have shown that training and experience in obtaining and preparing the samples play a major role in the efficacy of the method (Lee et al, 1987A and B; Palombini et al, 1988; Layfield et al, 1989; Ljung et al, 2001). It is much easier to interpret FNA samples microscopically if they are abundant, representative, and well prepared. Optimal samples will contribute greatly to a very high degree of diagnostic accuracy. Thus, operators who are well trained in the sampling technique of various body sites will serve patients better (Shah et al, 1999; Rodrigues et al, 2000).

The FNA sampling technique is essentially the same for all organ sites, and can be applied to both palpable and nonpalpable lesions. In the latter case, the needle is guided to the target area by the use of various imaging modalities. Immediate examination of the cell harvest at bedside, using a quick staining procedure, ensures that representative material is obtained, and thus reduces the number of samples necessary for diagnosis (see below). The main **objectives of aspiration biopsy are to distinguish benign from malignant lesions, and to classify neoplasms and other pathologic processes.** Well-prepared, representative material is necessary for these objectives to be consistently achieved.

Critics of aspiration biopsy have emphasized the serious consequences of a false-positive diagnosis. The quality of the material plays a crucial role in avoiding this problem. The most **common scenario for a false-positive diagnosis** is that of a cytopathologist attempting to interpret scanty material that contains only a few abnormal cells. The situation may be further compromised by artifacts caused by improper smear preparation, and by the clinician's insistence on a definitive diagnosis. A diagnosis of cancer must be based on ample evidence present in several different areas of the slide or in multiple slides. If a conclusion cannot be reached because of scanty or poorly preserved material, a descriptive diagnosis followed by re-aspiration or another diagnostic procedure is appropriate.

False-negative diagnoses most often are related to sample quality. The needle tip may not have been properly placed in the lesion, resulting in failure to obtain adequate material. The smears may show only benign structures from an area adjacent to the tumor.

The precise classification of a neoplasm generally requires more abundant and better-

preserved material than does the differentiation between benign and malignant lesions. It is often necessary to study the architecture of cell clusters, as well as the nuclear and cytoplasmic features of individual cells. The success of the diagnosis depends on representative, **ample**, well-prepared material. Good judgment is particularly important for assessing specimens with unusual cytologic or clinical features.

Knowledge of the clinical **history and presentation** of the target lesions is part of the cytologic evaluation. If the cytologic material does not match the clinical findings, additional procedures may be required. For instance, if the clinical findings identify a breast mass suggestive of cancer, but the aspirate smears show only a few benign cells, it is likely that the lesion was not sampled correctly and should be reaspirated. On the other hand, if the **breast lesion sampled is nodular and oblong by palpation, and the needle tip encounters firm fibrous resistance typical of fibrocystic change**, a moderate number of **clusters of well organized** benign breast cells can be considered diagnostic of a benign disorder. If aspiration biopsy is used to confirm a benign lesion that does not require surgical removal, the lesion must be followed, preferably **by clinical examination for 3-6 months**. If the sampled mass grows larger or becomes firmer, or if its outline changes, additional sampling or a surgical biopsy should be performed. In one study, 60% of benign breast masses disappeared within 2 years (Sainsburg et al, 1988).

The purpose of this chapter is to provide an overview of the various aspects of the aspiration technique, such as indications for use, patient preparation, and possible side effects. Various sampling and smear preparation procedures will be described. The pitfalls of the technique and the means to avoid them will be discussed.

EQUIPMENT, PATIENT SELECTION, AND PREPARATION

Needles

Ordinary disposable hypodermic needles with long bevels are well suited for aspiration. The needles may vary in size from 22 to 27 gauge (outer diameter from 0.65 to 0.5 mm) (Fig. 28-1). The choice of gauge is a matter of personal preference, and to some degree depends on the situation. For example, larger-diameter needles may be needed for the evacuation of extremely viscous fluid. The **larger-bore needles** collect somewhat more material from loosely structured cellular organs (such as the normal liver) or lesions (such as most melanomas, small-cell tumors, and lymphomas). On the other hand, the **smaller-bore needles are more effective for sampling tissue with few epithelial cells and extensive fibrosis** because they penetrate the stroma more easily and are more effective in securing the epithelial cell component. Typical examples of this situation include invasive lobular carcinoma and fibrocystic change with the dominant fibrous component in the breast. Specially designed nonmagnetic needles can be used to sample lesions visualized by **magnetic resonance imaging (MRI)**. Longer needles, provided with a needle guide and a trocar, are required to reach deep-seated thoracic or abdominal lesions visualized by computed tomography (CT), ultrasound, or fluoroscopy.

Syringes, Syringe Holders, and Other Items of Equipment

Slip Tip disposable syringes with an eccentric tip (Becton Dickinson & Co., Franklin Lakes, NJ) are recommended because of the ease of removing and reattaching the needle (Fig. 28-1).

Leakage of air from these syringes has not been a problem in my experience.

Figure 28-1 Instrumentation needed for thin needle aspirates of palpable lesions, showing needles of various lengths, a syringe with an eccentric tip, and a Franzén single hand-grip syringe holder.

A syringe holder can be used when a free hand is needed to stabilize the palpable target during sampling. Several types of syringe holders are available (some examples are shown in Fig. 28-2). Prices vary; however, most syringe holders are reusable and are durable enough to last for a lifetime. The syringe holder should hold the syringe firmly, be comfortable to hold and easy to clean, and not slip easily out of position. It should allow for removal of the needle and retraction of the plunger without the necessity of removing the syringe from the holder.

Figure 28-2 Examples of syringe holders for the fine-needle aspiration biopsy.

A syringe holder that fits a 10-ml rather than a 20-ml syringe is easier to handle. The shorter 10-ml syringe decreases the distance between the hand and the target, making sampling easier. There is no significant advantage to the larger syringe, because only minimal suction (a vacuum of 1-2 ml) is sufficient to obtain the sample. A 20-ml syringe may be more convenient when aspirating cysts containing fluid volume in excess of 10 ml. However, in the case of a large cyst that exceeds the capacity of the syringe, the needle tip can remain within the cyst while the full syringe is removed and replaced by an empty one. This procedure can be repeated as often as necessary until all of the fluid is evacuated. **The needle, syringe, and the syringe holder must be assembled before the procedure is started.**

A pencil-grip syringe holder was developed by Tao and Smith (1999). The **Tao Aspirator** (Tao and Tao Technology, Inc., Carmel, IN) is easy to handle and offers a presetting of negative pressure to achieve adequate suction.

A supply of clean microscopic slides, coverslips, alcohol scrubs, fixatives, ingredients for rapid stains, sterile gauze, and bandaids must be available before the procedure is initiated (Fig. 28-3). Slides with **frosted ends are desirable for identifying patients with a pencil.**

Patient Selection

One of the great advantages of aspiration biopsy with thin needles is that it can be applied to almost any patient regardless of physical status, **except for clotting disorders** in deep-seated targets. The procedure causes few and mostly insignificant side effects, and only slight discomfort.

Contraindications

Sampling of carotid body tumors and pheochromocytomas may cause syncope and episodes of acute hypertension

P.1059

(McCorkell and Niles, 1985). If clinical symptoms and physical examination suggest a carotid body tumor, CT (or MRI) will often provide sufficient diagnostic information to proceed with

surgical removal (Olsen et al, 1987; Som et al, 1988). The same approach should be used in pheochromocytomas.

Figure 28-3 Equipment for fine-needle aspiration. There are bottles with 95% ethanol for fixation of smears and of toluidine blue stain. A box of cover glasses is used for smear evaluation at the bedside. Syringe, needles, alcohol swab, gauze for hemostasis, bandaid, gloves, a pencil for marking slides, and glass slides with paper clips to keep them separated when placed in fixative are essential parts of the equipment.

There are very few other definite contraindications to FNA. Most often it is a matter of weighing alternative risks and choosing the safest diagnostic alternative. In many cases, the FNA, in spite of certain risk factors, is the safest diagnostic procedure for a given patient. Some contraindications are controversial. Ovarian cyst aspiration, for example, is considered by some to be contraindicated because of the risk of leakage and associated dissemination of disease in the peritoneal surface (Trimbos and Hacker, 1993), while others recommend cytologic investigation of ovarian lesions (Kreuzer et al, 1985). Most would agree that FNA of prostate should not be done in patients with obvious prostatitis (Espoti, 1975).

Serious complications in the aspiration of **hydatid cysts**, which may result in anaphylactic shock, have also been described. Hemorrhagic diathesis, extremely vascular lesions, and the patient's inability to cooperate may be considered contraindications to deep-seated FNA. Likewise, severe emphysema, pulmonary hypertension, and conditions associated with severe hypoxemia are contraindications to FNA sampling of chest lesions (Green, 1982).

Patient Preparation

For most aspiration procedures, the only **patient preparation** needed is an explanation of the procedure and a discussion of possible side effects. **Informed consent** must be obtained. **For superficial lesions, local anesthesia is optional**, as the discomfort caused by its application is about the same as that of the aspiration itself. Furthermore, when very small targets are sampled, the injected anesthetic may make it more difficult to feel the mass and consequently to correctly place the needle.

Local anesthesia is **routinely** employed **when sampling deep-seated targets** with the aid of CT or ultrasonic guidance. These procedures tend to last longer and be more painful than aspiration of superficial targets: the needle has to travel a longer distance, several attempts may be needed to position the needle correctly, and the needle tip must often pass through muscle, which is especially sensitive to needle sticks.

A simple **disinfection protocol** of wiping the skin at and around the biopsy site with an alcohol-soaked swab is sufficient for superficial lesions. For deep-seated lesions, it is common practice to cleanse a larger area of skin and use sterile gloves and draping. This facilitates the insertion of the highly flexible needle by allowing the operator to hold onto and stabilize the shaft during insertion.

BASIC ASPIRATION TECHNIQUE

The basic principles described in this section are applicable to aspiration biopsies of all organ sites. Technical considerations with regard to specific organ sites and specific clinical presentations will be discussed separately.

The **concept of aspiration** using the system of thin needles and syringes is somewhat **misleading**, as it implies that cells are being sucked into the syringe. Suction alone will work only when the targeted lesion contains fluid. When the lesion is solid, the **needle tip functions as a cutting instrument**: as it is moved to and fro, tiny tissue fragments become dislodged and collected inside the needle. When suction is added to this procedure, the previously dislodged fragments are sucked into the needle and the tip of the attached syringe (Fig. 28-4). **Except for fluids, the aspirate should not reach the barrel of the syringe**, because it will be difficult to retrieve.

Palpable Lesions

Requirements for obtaining adequate samples via aspiration biopsy include **target palpation, immobilization, and proper needle tip placement and movement**. The following protocol is suggested when sampling **palpable** lesions:

- **Palpation of the Target and Planning of the Procedure.** The target should be carefully palpated, and its size and distance from the overlying skin should be assessed. These determinations govern the placement of the needle tip. In **small lesions** (1 cm in diameter), it is generally desirable to aim for the **center of the lesion**. In **very large lesions** (>5 cm in diameter), there may be central necrosis, and thus **the periphery is more likely to yield diagnostic material**. In **medium-sized lesions** (2 to 4 cm in diameter), it is often advantageous to **collect samples from two different areas**: one to the

P.1060

side of the center, and another one in the mirror-image position of the previous aspiration. This approach will yield a more representative harvest. Also, the second sample is extracted from an area not previously disturbed by the needle, thereby decreasing the likelihood of contamination with excessive amounts of blood.

- **Immobilization of the Target.** To collect an adequate sample, **the target should not move with the needle**. It is particularly important to **immobilize lesions with dense stroma** in order to facilitate penetration of the needle tip into the target. Lesions over 3 cm in diameter can be held in place with the thumb and forefinger. Smaller lesions (1 to 2.5 cm) can be more effectively immobilized between the forefinger and middle finger (Fig. 28-5). Note that the fingers should be placed very close to the lesion. Stretching the overlying skin tightly

across the lesion further helps immobilize the target. Very small lesions (<1 cm in diameter) are often difficult to stabilize and sample. To immobilize these small targets, they should be palpated with the tips of the forefinger and middle finger held tightly together. The target should be pushed as far as possible in one direction in the subcutaneous space. Then, without lifting the finger-tips, the overlying skin must be retracted. The pressure will cause the lesion to “pop up” under the skin surface in front of the fingertips (Fig. 28-6). Without moving the fingers, cleanse the skin with an alcohol swab or other disinfectant prior to aspiration.

- **Insertion of the needle.** Once the target has been secured, the previously assembled aspiration instrument must be picked up and the needle tip inserted into the target (Fig. 28-7A). Suction is applied by retracting the syringe plunger to the 1- to 2-ml mark. This level of suction is sufficient; however, more suction should not alter the outcome. It is best to find a position for the plunger that is comfortable, and to **keep the suction at this level throughout the sampling period.** Pumping the plunger up and down during the procedure should be avoided, as it detracts from essential needle movement and does not add to the quantity or quality of the sample.
- **Aspiration procedure.** Once suction has been applied, **the needle tip must be moved back and forth (or up and down)** within the boundaries of the target (Fig. 28-7C). If the target is not spherical, the longest axis possible for the needle tip movement should be used. To collect sufficient material for at least two smears, typically **15 to 20 needle movements are required.** If significant amounts of blood appear at the hub of the needle, it is best to limit the number of needle movements to about five in order to avoid excessive dilution with blood. If the needle is not moved, usually only blood will be aspirated. If after about 10 movements, blood starts to appear, the sampling should be ended for optimal results (see below for how bloody samples should be handled). It is usually best to **move the needle in approximately the same plane, particularly in small targets.** The needle will tend to travel in a slightly different

P.1061

plane without a conscious effort on the part of the operator. **In larger targets, the angle of the needle may be changed in small increments during sampling. Major changes in the direction of the needle must be avoided** because they may cause bleeding, unless the procedure outlined below is carefully followed. Using this approach, optimal amounts of tissue will be collected in a short time with minimal bleeding and discomfort. **At least one additional aspiration** should be performed routinely to ensure representative sampling. **However, if the first sample shows unequivocal evidence of a malignant tumor (by immediate assessment at the bedside), no further sampling is necessary unless material for special studies is required.**

- **Withdrawal of the needle.** After collecting the sample, **release the suction before withdrawing the needle** (Fig. 28-7D,E). This allows the collected material to stay within the needle and syringe tip. If suction is maintained while the needle is withdrawn, the collected material will be sucked into the barrel of the syringe and will be difficult to expel. After the needle is withdrawn from the lesion, remove the needle from the syringe (Fig. 28-7F) and pull back on the plunger (Fig. 28-7G). Then reattach the needle (Fig. 28-7H) and expel the material onto a glass slide by pushing the plunger swiftly through the syringe (Fig. 28-8). In order to **avoid splattering, the tip of the needle should rest on the slide.**
- **Changing the direction of the needle.** Occasionally, a significant change in the direction

of the needle path may be desired during sampling. To accomplish this maneuver, the needle tip should be **withdrawn from the target while it remains under the skin. The angle of the needle is changed *before* the needle is reinserted**

P.1062

into the target (Fig. 28-9). Suction need not be released. If the needle is not withdrawn before the direction is changed, the target may merely be pushed to the side and the intended redirection of the needle tip will not be accomplished. The patient may also experience unnecessary discomfort and bleeding. Dramatically changing the direction of the needle during sampling requires additional time and skill, and, in my opinion, does not improve the harvest in most cases; therefore, it is not recommended as a standard procedure. An example of a lesion for which a change in the direction of the needle may improve the harvest is an **ill-defined area of thickening** that requires extensive sampling. This situation occurs most commonly when sampling the breasts of postmenopausal women. Usually the needle will meet with only slight resistance upon insertion, corresponding to adipose tissue. By **changing the angle of the needle gradually throughout the thickened area**, the chances of sampling areas containing epithelial cells increase substantially. In fact, the needle tip may be used as a “palpating” probe to seek out areas of increased resistance that are more likely to contain epithelium and abnormal components than the surrounding fat tissue.

Figure 28-4 The needle tip is moved back and forth inside the lesion, dislodging and collecting small fragments of tissue.

Figure 28-5 Immobilization of small lesions (1 to 2.5 cm) using the forefingers and middle fingers. Stretch the overlying skin and hold it down firmly, preventing the lesion from moving during the procedure.

Figure 28-7 Aspiration sampling technique. *A.* Place the needle tip in the lesion. *B.* Pull back the plunger to create suction and hold the plunger steady throughout the sampling procedure. *C.* Move the needle back and forth inside the lesion up to 10 to 20 times. *D.* Release suction by letting the plunger go. *E.* Withdraw the needle. *F.* Remove the needle from the syringe. *G.* Fill the syringe with air by pulling the plunger as far as it will go. *H.* Reattach the needle.

Figure 28-8 Expel the harvest on the slide by swiftly pushing the plunger through the syringe. The needle tip should be in contact with the glass to avoid splatter.

Figure 28-9 Redirection of the needle during sampling. After sampling one part of lesion (*A*), pull the needle tip back to the proximal surface of the lesion (*B*), redirect the needle (*C*), and advance the needle in order to sample a different part of the lesion (*D*).

Nonpalpable Lesions

The aspirations are performed under stereoscopic imaging guidance. The principles of aspiration described above for palpable lesions must be observed.

ASPIRATION WITHOUT A SYRINGE

Zajdela et al (1987) described a sampling technique that uses a thin needle without suction. The target is identified and immobilized as described above. Then the needle, held by the hub, is placed within the target and moved back and forth to collect small fragments of tissue. The

fragments **are collected within the shaft of the needle. The hub-opening of the needle should be left uncovered during sampling.** The main advantage of this technique is the ease with which the needle can be accurately positioned in the target. The thin needle is also easier to manipulate when it is not attached to a syringe. This simple technique also often enhances the differences in consistency between lesional tissue and the surrounding normal tissue. In addition, sampling without suction may reduce the amount of blood when highly vascular lesions or organs are sampled. Typically, the volume of the harvested material is usually smaller than that obtained by procedures that apply suction. However, the smaller volume may be more representative of the lesion. Sampling without suction may be especially useful in small, highly vascularized targets, such as the thyroid, and in other sites with abundant blood supply. This technique is not recommended for aspirating cystic lesions containing fluid.

SIDE EFFECTS AND COMPLICATIONS

Superficial Targets

The most common complication associated with FNA of superficial targets is local hematoma in and around the mass. The bleeding may occur during the sampling or for a few minutes after withdrawal of the needle. The size of the hematoma can be minimized by applying firm pressure to the mass and the surrounding area immediately following the sampling. It is usually most effective to have an assistant apply the pressure. If no assistant is available, the patient should be carefully instructed how to apply pressure before the procedure is initiated. If the patient has a bleeding disorder or is taking any type of medication that interferes with blood clotting (such as Coumadin and nonsteroidal anti-inflammatory drugs, including aspirin), the post-aspiration pressure should be extended for up to 10 minutes.

Any hematoma will make the palpable mass seem larger after the procedure, and typically the patient will experience minor discomfort, which usually peaks the day following the procedure. Thereafter, both the swelling and discomfort will gradually disappear, and are usually resolved within 3 to 7 days. Usually no intervention is needed, but on occasion a cold pack and/or an analgesic, such as acetaminophen, may be indicated. On extremely rare occasions, hematomas following

P.1063

FNA may be large and may cause transient nerve paresis (for example, in the recurrent nerve adjacent to the thyroid gland).

Local infection is extremely rare and can be treated with antibiotics. No serious infections following FNA of superficial targets have been reported.

On very rare occasions, FNA of superficial targets located near the chest wall, such as breast masses and lymph nodes in the axillary and supraclavicular locations, may cause pneumothorax (Chen, 1986). The patient typically experiences immediate pain and discomfort in the chest and/or shoulder. Most pneumothoraces are small and resolve spontaneously. Pneumothorax can be avoided by sampling with the needle positioned tangentially relative to the chest wall.

Deep-Seated Targets

The complication rates for deep-seated targets are higher than those for superficial targets, and occasional fatalities have been reported (Esposti et al, 1975; Livraghi et al, 1983; Droese et al, 1984; Malberger et al, 1984). However, the rate of complications is still extremely low when compared with surgical or core needle biopsy procedures that carry a much higher risk. As with

superficial targets, **bleeding** is the most common complication. It is a more serious issue in the deep-seated targets, mainly because local compression cannot be applied to stem the bleeding. Serious bleeding is most likely to occur if the needle tip lacerates the liver or splenic capsule. The risk of laceration is significantly increased if the patient is not able to cooperate with breathing instructions. To minimize the risk of serious hemorrhage, the patient's coagulation parameters should be evaluated before the procedure. It is sometimes advisable to temporarily stop medication that interferes with coagulation to reduce the risk of hemorrhage. Although bleeding rarely has serious consequences, the patient should be told that the aspiration procedure may result in hemoptysis, hematuria, hematospermia, or bloody discharge from the rectum or vagina, depending on the location of the target of the FNA.

The Thorax

Pneumothorax is the most common significant complication from FNA of targets within the thorax (Green, 1982). The vast majority of pneumothorax cases resolve spontaneously. Pneumothorax may also result from FNA in the upper abdomen if the needle tip accidentally penetrates the diaphragm and enters the pleural space. A rare but very serious complication when sampling the lung is systemic arterial **air embolism** (Aberle et al, 1987).

The Abdomen

In the abdomen, very rare but potentially serious complications **include necrotizing pancreatitis** (Evans et al, 1981), **biliary peritonitis, bowel perforation, and localized peritonitis** (Malberger et al, 1984). An obstructed and thus distended biliary system and intestine may be vulnerable to leaking and should be avoided. We observed a case of biliary peritonitis in a patient with distended **Curvoisier gall bladder** (Koss et al, 1992). However, in the vast majority of cases the penetration of bowel, vessels (including large arteries), and other abdominal structures with 22-gauge or thinner needles causes no significant damage. The hole created by the needle is smaller than those caused by sutures commonly used during abdominal surgery.

Infections in Transrectal Sampling

Although overall infection after FNA is exceedingly rare, it is a significant issue when performing transrectal FNA, particularly of the prostate gland (Esposti et al, 1975). There is some evidence that prophylactic antibiotics administered before the start of the procedure are protective. Fever over 101°F (38.5°C) that develops after transrectal sampling should be treated promptly and aggressively. Sampling the prostate in patients with symptoms of acute prostatitis should **not** be done.

Infarction

Complete or partial infarction of tumors and lymph nodes as a result of FNA may occur but is very rare. Most common sites reported are thyroid masses, tumors of the salivary gland, and lymph nodes (Davies and Webb, 1982; Jones et al, 1985; Kern, 1988; Jarayan and Agarwal, 1989; Keyhani-Rofagha et al, 1990; Kini, 1996; Mukurnyadzi et al, 2000). We have also recorded a case of infarction of a lymph node. In most cases, the necrosis is not complete and a histologic diagnosis can be rendered. Us-Krasovec et al (1992) noted that tissue necrosis usually occurs if the lesion is sampled with multiple needle passes.

Tumor Implantation

Implantation of tumor along the needle track has been reported for both 22-gauge and thinner needles used for FNA as well as for core needles, 18 gauge and larger. Larger-bore needles carry a much higher risk of causing tumor seeding, and it has been estimated that increasing the diameter of the needle by a factor of 2 increases the seeding risk by a factor of 60 (Roussel et al, 1989). The most common sites of tumor implantation in needle track include the chest wall (Sinner and Zajicek, 1976; Moloo et al, 1984), the thyroid gland (Hales and Hsu, 1989; Karwowski et al, 2002), the kidney (Kiser et al, 1986; Wehle and Grabstald, 1986), and the pancreas (Smith et al, 1980; Caturelli et al, 1985; Rasleigh-Belcher et al, 1985). Although seeding of tumor in the needle track is of concern, it is not known whether this complication significantly changes the disease outcome for these patients. DeMay (1996) provided a comprehensive summary of published cases with documented tumor implantation.

Of more concern may be the possibility that tumor cells will be disseminated outside the primary tumor by FNA sampling, thus increasing the risk of metastatic disease. Two studies investigated the impact of FNA on long-term survival in patients with primary breast cancer (Berg and Robbins, 1962; Taxin et al, 1997). Neither study found any adverse effects of FNA.

P.1064

Diagnostic Problems in Histopathology After Aspiration Biopsy

LiVolsi and Merino (1994) described a distortion of histologic patterns in the thyroids, mimicking carcinoma, after aspiration biopsy. We have treated many thousands of patients and have not experienced this problem. However, infarction of the tumor or a lymph node after aspiration may cause interpretative problems, particularly in the diagnosis of malignant lymphoma. In such a case seen by us, a second biopsy of a lymph node was required to establish the diagnosis.

BASIC SMEAR PREPARATION TECHNIQUES

The goal of smear preparation is to allow optimal distribution of well-preserved cells and small tissue fragments on the slide. Several different basic smearing techniques have been described. All have their advantages and disadvantages, and will produce different artifacts. The choice of smearing technique is partly a matter of preference, and most operators favor one method over another. Here, a one-step smearing technique will be described in detail and other methods will be mentioned briefly. The description is based on slides with frosted ends.

One-Step Technique

The basic one-step smearing technique (Abele et al, 1985) is designed to process a harvest consisting of one or two droplets of semisolid tissue material. A small amount of blood (one or two drops) may also be included. The non-dominant hand steadies the needle as the needle tip, bevel down, is touched to the frosted (proximal) end of a clean slide. The harvest (or part of it) is expelled onto the slide in the form of a droplet (see Fig. 28-8). Next, the slide is picked up by its frosted end between the thumb and forefinger of the nondominant hand. The other fingers are used to create a steady platform beneath the slide. A clean slide is then held by its frosted end in the dominant hand (Fig. 28-10A). Its lower long edge is placed against the first slide at a 45° to 90° angle proximal to the droplet (Fig. 28-10B). This top edge of the slide is then lowered until it touches and then covers the droplet and the two slides are flush (Fig. 28-10C). At this point, the material is spread in one smooth motion by pulling the top slide along the entire length of the bottom slide (Fig. 28-10D). The movement should be smooth and fairly rapid but not hurried. It is **very important to keep the two slides parallel to each other** during smear preparation to avoid scraping the bottom slide (Fig. 28-11). As soon as the smear has

been prepared, the first (bottom) slide should be fixed. Any delay in fixation will result in air-drying artifacts. The second (top) slide used for smear preparation usually contains no diagnostic material and can be reused to make several smears from the same harvest.

When the droplet is large enough, the material can be **divided to prepare additional smears**. To divide the material, the two slides are initially positioned as for the one-step smear technique. The top slide is then gently rotated down until it just touches the droplet, thus picking up a portion of this material. The two slides are then separated. The top slide is kept in the dominant hand and is used to prepare a smear via the one-step method described above, using a new clean slide as the bottom slide. Finally, a smear is made of the original droplet, again using the one-step technique.

An **alternative method** of smear preparation is to put a clean slide on top of the slide holding the expelled material and then pull the two slides apart sideways. **Another variant of smear preparation** involves placing a second slide over the slide holding the aspirated material and then lifting it

P.1065

straight up. These two techniques are easier to master than the one-step technique, but in my experience the one-step technique results in better smears.

Figure 28-11 Method of smear preparation: the two slides must be kept flush throughout the smearing process to avoid scraping artifact.

Material Diluted With Blood or Other Fluids

Dilution of the diagnostic material with excess fluid (usually blood) is by far the most common reason for difficulty in smear preparation. Several techniques can be used to process such specimens. The goal is to separate tissue fragments from the fluid prior to smear preparation. Two techniques that can be used in a complementary fashion will be described in detail; others will be mentioned briefly.

When expelling material diluted with fluid, it may be necessary to spread it over several slides. The slides containing most tissue fragments can be easily identified. The best slide should be selected first and held in the nondominant hand by its frosted end (Fig. 28-12A). The slide is tilted toward the preparer so that the fluid runs down along the long edge of the slide and the tissue fragments remain in the center (Fig. 28-12B). The short edge of a second clean slide is then used to remove these fragments (Fig. 28-12C,D). The second slide with tissue fragments

is placed at a 45° to 90° angle against a third clean (bottom) slide, rotated down until it is flush with the bottom slide, and then pulled along the length of the bottom slide along a parallel course (Fig. 28-12E-G; see also Fig. 28-11). This process may be repeated, collecting additional fragments from the original slide.

Figure 28-12 Concentration and smearing of the diluted harvest (*A*) part I. *B*. Tilt the slide. *C,D*. Use a clean slide to remove stranded fragments. *E*. Replace the bottom slide with a clean slide. *F*. Position the slides at an angle and rotate the top slide until it is flush with the bottom slide. *G*. Smear by sliding the top slide, keeping it flush with the bottom slide.

Another method for handling material diluted by excessive fluid is a **two-step technique** (Abele et al, 1985). As in the previous method, the best slide (i.e, the slide containing visible fragments of tissue) is selected. This slide is held in the nondominant hand with its frosted end tilted down and away from the preparer (Fig. 28-13A). This allows the excess fluid to flow down toward the frosted area, leaving behind tissue fragments over the surface of the slide. A clean slide is then used to move the tissue fragments and remaining fluid, first toward the frosted end of the first slide and then back to the middle of the bottom slide (Fig. 28-13B-E). The top side is removed (Fig. 28-13F) and the tilt of the bottom slide is then increased slightly to allow the

remaining fluid to run off (Fig. 28-13G). Fragments of tissue have thus been collected in a row across the middle of the bottom slide, and most of the fluid has been drained. The fragments may then be smeared by the one-step technique, using a clean slide (Fig. 28-13H,I).

Excess fluid can also be removed with the use of a **gauze pad to soak up part of the fluid** before smear preparation. The harvest may also be placed in a watch glass, and a round coverslip may be used to retrieve the tissue fragments.

P.1066

Figure 28-13 Concentration and smearing of the diluted harvest, part II. *A*. Tilt the slide with the harvest end toward the frosted end. *B-E*. Transport the fragments and remaining fluid toward the frosted end without lifting the slide or changing the angle; transport the gathered fragments to the middle of the slide. *F*. Lift the top of the slide. *G*. Tilt the bottom slide further to allow the fluid to run off. *H*. Place the top slide at an angle and rotate it until it is flush with the bottom side. *I*. Smear the fragments by sliding the top slide. Keep the two slides flush.

FIXATION AND STAINING OF ASPIRATED MATERIAL

The most commonly used stains for smears of aspirated material are the **Papanicolaou, hematoxylin-eosin**, and **Romanowsky-type stains**, such as May-Grünwald-Giemsa (Fisher Co.), Wright-Giemsa (Fisher Co.), and Diff-Quik (Allegiance) (see Chap. 44 for staining methods). Table 28-1 compares these stains.

The Papanicolaou stain requires immediate fixation in alcohol before the smears start to dry. Ethanol (95%) is most commonly used; methanol in a 70% to 95% solution also produces good results. Smears intended for Romanowsky-type stains are air-dried before the staining procedure is initiated, and can be stored indefinitely in their unstained state.

Of the Romanowsky-type stains, the May-Gruenwald-Giemsa and Wright-Giemsa stains, when applied by immersion, appear to yield the best results. The Diff-Quik and Wright-Giemsa stains, when applied by automatic stainer, often fail to penetrate sufficiently into cell clusters. This problem can be corrected by increasing the staining time.

Rapid Staining Techniques

A rapid staining technique is valuable for a preliminary evaluation of material before the patient is released. **The main purpose of rapid staining and microscopic review at the bedside is to ascertain that adequate material has been collected. This approach facilitates the decision as to whether to collect additional material for special studies in selected cases. In addition, in many cases a preliminary diagnostic assessment can be made.** Several **rapid stain** options are available, including a fast version of the Papanicolaou method, the hematoxylin-eosin stain designed for frozen sections, Diff-Quik or May-Grünwald-Giemsa stains with the staining time reduced to 2 minutes for each, and **toluidine blue, which is by far the fastest.**

Briefly, the smear is immersed in alcohol for at least 15 seconds. One to two drops of **toluidine blue solution** (0.05 g toluidine blue powder, 20 ml 95% alcohol, and 80 ml distilled water, mixed and filtered before use) are applied to the smear, which is wet-mounted with a coverslip. After the stain is allowed to penetrate for 10 to 15 seconds, the slide is turned over onto a paper towel or other absorbent material with the coverslip in place, and excess stain is removed by applying **moderate** pressure to the slide. The slide is ready for a preliminary evaluation in about 1 minute. After microscopic evaluation, the slide is reimmersed in alcohol. The coverslip will fall off and the slide can be stained by the **Papanicolaou or hematoxylin and eosin** method. The alcohol will remove the toluidine blue from the cells. If an abbreviated version of the May-Gruenwald-Giemsa stain (such as the Diff-Quik) is chosen, the stain will be less intense than when applied in the standard manner; however, the smears may be restained using the standard protocol. For details regarding stain preparation and usage, see Chapter 44.

Liquid Processing of Aspirates

The collection of material in liquid media, and processing by one of the two FDA-approved methods (ThinPrep; Cytoc Corp., Boxborough, MA; and SurePath, TriPath Imaging, Inc., Burlington, NC) have been applied to aspirated samples. Michael et al (2001) noted that SurePath offers a somewhat better preservation of architecture of cell clusters and cellular integrity than ThinPrep. Kurtyn and Hoerl (2000) cautioned against the indiscriminate use of thinlayer technology. Serious reservations about the use of this technique were also expressed by Michael and Hunter (2000)

who also pointed out that the ThinPrep technique leads to artifacts and diagnostic pitfalls. Salhadar et al (2001) concluded that routine use of the ThinPrep technique for aspiration biopsy is diagnostically not justified.

TABLE 28-1 COMPARISON OF MAY-GRUENWALD-GIEMSA (MGG), HEMATOXYLIN-EOSIN, AND PAPANICOLAOU STAINS			
Factors	MGG	Hematoxylin-Eosin	Papanicolaou
Preparation of material	Air-drying	Alcohol fixation	Alcohol fixation
Cytoplasmic features	Brings out a variety of cytoplasmic granules and inclusions	Offers little cytoplasmic differentiation	Brings out cytoplasmic keratinization
Nuclear features	Chromatin features difficult to assess; air-drying may induce artifacts	Tends to overstain nuclei unless carefully performed	Excellent identification of nuclear features
Nucleoli	Readily visible as pale intranuclear structures	Adequate, sometimes difficult to see in hyperchromatic nuclei	Adequate, sometimes difficult to see in hyperchromatic nuclei
Mucus and colloid	Well visualized	Require special stains	Require special stains
Familiarity to users	Stain familiar to hematologists	Stain familiar to tissue pathologists	Stain familiar to cytopathologists

However, cells collected in fluids are suitable for additional diagnostic procedures, such as molecular studies and proteomic profiles (Filie et al, 2001; Panizo et al, 2001).

Preparation for Special Studies

Aspirated material can be used in a number of special studies. **Cell surface markers** that are needed to characterize hematopoietic neoplasms can be identified on **aspirated material**. **Most commonly, this is done using either flow cytometry or a cytospin technique.** A quicker way to process aspirated material for cell surface markers is to use **cytocentrifugation.** **For both techniques, the aspirated cells are suspended in a growth medium, such as RPMI** (Tani et al, 1989; Sneige, 1990). Whichever technique is used, **properly collected cytologic material will allow for a wide battery of cell surface markers**

to be **examined** (see Chaps. 31 and 45).

Evaluation of the **estrogen and progesterone receptor** content and **molecular markers** in breast cancer can be done on cell blocks with the use of **staining techniques applied to histologic material** (Masood et al, 1990). Dardick et al (1992) and Guindi et al (1994) described in detail the application of immunocytochemistry and electron microscopy to aspirated samples. The material can also be used for sophisticated molecular studies and proteomics (Fille et al, 2001; Panizo et al, 2001).

Cell Blocks

As an option in specimen preparation, cell blocks may be prepared. This is particularly useful when special studies, such as immunohistochemical studies, are required for complete evaluation of the lesion (Zito et al, 1995). In my experience, leftover material from the needle, collected by washing after preparation of smears, seldom produces useful information that adds to the diagnostic evaluation. Instead, **I recommend using cell blocks in selected cases with a specific purpose. In such cases, I typically put aside one or several dedicated samples in order to ensure a rich, diagnostically meaningful specimen. The harvest may be placed in RPMI, a solution used for fluid-based cytology, or buttered formaldehyde.** The specimen should be examined against a light source. The presence of fragments of tissue in the fluid ensures a good cell block preparation. **I also find it helpful to include a few drops of blood in the specimen. The blood makes the specimen highly visible during processing of the paraffin block, and therefore less likely to be lost or cut suboptimally.** For details regarding cell block processing, see Chapter 44.

SPECIAL PROBLEMS IN ASPIRATION TECHNIQUE

A basic rule that applies to all aspiration sites is that the patient should be in a comfortable position that provides the operator with optimal access to the target. This may vary with the target organ; hence, several different positions and approaches may be considered before the aspiration is performed.

Thyroid Gland

In most instances, sampling a mass in the thyroid gland is easiest if the patient is in a position that allows the skin and muscles of the neck to be relaxed. The patient should lie flat on the back, either without a pillow or with

P.1068

a thin pillow under the head. A pillow under the neck or shoulders tends to stretch the tissues in the anterior portion of the neck, making it difficult to access the mass, especially if it is located deeply within either lateral lobe, away from the isthmus. **However, if stretching the neck brings the mass forward and makes it easier to palpate, then this is the best position for the patient to be in.**

To make sure that the mass is in the thyroid, I find it helpful to feel the mass move up and down on swallowing before sampling. Immobilizing a target in the thyroid gland is best achieved by **pushing the lesion against the trachea**, using the volar aspects of the forefinger and middle finger. The sternocleidomastoid muscle should be pushed to a lateral position and should not be allowed to cover the target (Fig. 28-14A). Passing through layers of muscle when inserting the needle adds significantly to the discomfort of the patient, while making needle placement more difficult and uncertain. Also, small fragments of muscle may plug the needle,

jeopardizing subsequent sampling of the target. Ideally, **the angle of the needle should be tangential to the trachea**. This way, the needle will be less likely to penetrate the trachea, with resulting loss of the sample in the barrel of the syringe. The tangential approach also allows easier sampling of small and/or flat lesions close to the trachea. **It is important for the patient to refrain from swallowing during the sampling. One way to achieve this is to ask the patient to swallow just before the needle is placed through the skin and into the target area.**

A common problem in sampling the thyroid is the presence of **blood diluting the specimen**. While it is often impossible to avoid some admixture of blood in the sample, several measures can be taken to minimize the amount.

Figure 28-14 A. Needle aspiration of the thyroid gland. The needle should be tangential to the trachea, and one should avoid passing through the sternocleidomastoid muscle. B. Needle aspiration of lesions located beneath the sternocleidomastoid muscle. The lesion must be stabilized by reaching around the muscle. Slide the thumb down slightly to expose the skin overlying the mass and then insert the needle.

- The needle should be moved **back and forth in one plane only**. Changing the plane of the needle, particularly when the needle is deeply embedded in the tissue, will increase the amount of blood in the specimen.
- If blood appears immediately upon entering the target, the **needle should be moved back and forth only four or five times before it is withdrawn**.
- Although the retrieved cellular component may be relatively sparse, there will be less blood in the sample, and acceptable diagnostic smears can be prepared.
- Since the first sample from any given area of a target usually contains the least amount of blood, it is often advantageous to perform two standard aspirations in different areas of masses measuring more than 1.5 cm in their greatest diameter. This will increase the chances of obtaining representative material.
- Sampling with a thin needle without suction, as described above, usually decreases the admixture of blood.

If, in spite of these precautions, the samples contain a significant amount of blood, the special preparation and smearing techniques described above should be used. A blood-rich sample

may also be submitted for processing as a cell block or a liquid-based preparation. For further comments on aspiration biopsy of the thyroid, see Chapter 30.

Deep-Seated Neck Lesions

It is not unusual for deep-seated neck masses to be at least partially covered by the sternocleidomastoid muscle. Patients with such masses often have an abnormal contour of the neck because the mass is pushing on the midportion of

P.1069

the muscle. Although the mass can be palpated through the muscle, it is usually difficult to appreciate its size or determine its outline. A better way to palpate a deep neck mass is to place the thumb on the anterior aspect of the mass between the sternocleidomastoid muscle and the larynx, and the index and middle fingers on the posterior aspect of the mass behind the muscle (Fig. 28-14B). Access to the mass can be facilitated by having the patient **turn his or her head** in the direction of the mass, **facing slightly downward to relax the muscle**. When the mass has been palpated and immobilized, one can perform the aspiration by sliding the thumb down slightly, if necessary, to expose the skin overlying the mass. This approach allows better sampling and avoids painful penetration of the muscle. Collins et al (1998) reported an excellent correlation between FNA of neck masses and positron emission tomography (**PET**) in sampling deep-seated metastases.

Small Targets Adjacent to Major Blood Vessels

The most common example of a small target located near a major blood vessel is a small neck lymph node adjacent to the carotid artery. Sampling of these lesions must be done very carefully to avoid penetrating the wall of the vessel. Although the puncture of a vessel is not life-threatening, it may void the purpose of the aspiration, for several reasons:

- Penetration of an arterial wall is quite painful for the patient.
- If a significant amount of blood is aspirated, the cellular material is almost always lost.
- Bleeding into the adjacent tissue makes repeated sampling of a small target difficult, if not impossible; a delay of 10 to 14 days for the hematoma to resolve may be required before another aspiration can be attempted.
- There is also the theoretical possibility that a preexisting atheromatous plaque will be dislodged in the artery; however, to date there are no published reports of such an occurrence. **Penetration of the blood vessel can be avoided by carefully identifying the vessel's outline and positioning the needle tangentially to it** (Fig. 28-15).

Breast

Most solid breast masses are palpable with the patient lying down. This position is also the most convenient for sampling. **Sometimes, however, a breast mass may be palpable only when the patient is sitting in an upright position**. In such rare cases, the aspiration can be performed with the patient sitting either straight up or leaning slightly forward. An assistant can make the patient more comfortable and prevent her from moving backward during the biopsy by providing support to the shoulders.

The nipple and the areola of the breast are most sensitive to pain from a needle stick. These areas should be avoided whenever possible. Masses in these areas can sometimes be pushed away from the nipple, immobilized, and sampled through adjacent skin. Subareolar

masses that cannot be relocated should be approached laterally with application of a local anesthetic (Fig. 28-16). When a breast mass is located close to the chest wall, there is the possibility that the needle will penetrate it and cause a pneumothorax. This can be avoided by moving the mass sideways so that it rests on a rib. This not only prevents penetration of the chest wall, it also provides good support for immobilizing the target lesion. If the target cannot be moved into a safer position, the angle of the needle should be adjusted: Instead of approaching the chest wall at an angle of 90° , a more tangential approach may be used (Fig. 28-17). These techniques are applicable to any small mass located anywhere on the chest wall.

Several reports have described the use of **stereotactic mammography devices** for sampling nonpalpable breast lesions (Nordenstrom et al, 1981; Azavedo et al, 1989) (also see Chap. 29). Briefly, the breast is compressed, as during a routine mammography, between two plates. The posterior plate is firmly fixed to its support and has an engraved, radiopaque millimeter scale that corresponds to a 50 ×

P.1070

50-mm window in the anterior plate. The breast is placed between the plates, with the lesion visible within the window. Two exposures are taken, 15° apart. The position of the lesion is entered into a computer, which calculates the correct angle and depth for the position of the tip of the needle. After the needle is inserted, two additional stereoradiographs are taken to confirm the correct placement. Once the needle is positioned accurately, a cell sample can be obtained by the customary aspiration technique. The procedure may be repeated to collect additional material.

Figure 28-16 Needle aspiration of lesions near the nipple. The movable target should be pushed away from the nipple and aspirated from the side. The areola must be avoided.

Figure 28-17 Needle aspiration of small lesions in the chest wall. Position the needle at an angle tangential to chest wall, in order to avoid pneumothorax.

High-resolution ultrasound is becoming more common as a diagnostic technique in breast and other organs (Bentz et al, 1998). It is also a very valuable tool that can be utilized to guide the needle tip into the target. It allows visualization of the needle tip, in real time, as it moves through the target and secures the sample. This approach provides additional evidence that the sample is truly from the correct target area. Ultrasound guidance is particularly suited for nonpalpable breast masses that are visible on ultrasound. For further comments on aspiration of the breast, see Chapter 29.

Cystic Lesions

Cysts may occur in various organs and in many configurations, each of which requires a different approach. The most common cystic lesion sampled by aspiration is a **benign monolocular breast cyst** with a thin, fibrous capsule. The fluid is usually slightly opaque and ranges in color from light yellow (straw-colored) to dark green. This type of cyst should be followed clinically and no further therapeutic action is required if no palpable mass remains after the aspiration, unless there is a recurrence. If there is a residual mass after the fluid has been evacuated, it should be reaspirated or examined by a surgical biopsy. This applies to any aspiration site, not only the breast. **If the breast cyst fluid contains blood that is not obviously the result of sampling trauma, a tissue biopsy should be performed, unless a neoplastic process can be diagnosed in the aspirated material.** The thyroid gland also commonly harbors cystic lesions, whether benign or malignant. The aspirated fluid may show evidence of bleeding, but the epithelial component may be absent. If the cyst collapses after aspiration but recurs, it is advisable to remove it surgically.

In the case of multiple or multiloculated cysts, several aspirates may be necessary in order to evacuate the fluid and allow for effective sampling of any adjacent solid areas.

Intracutaneous Lesions

The most common example of an intracutaneous tumor is recurrent or metastatic **breast cancer**, usually in a location close to the previous mastectomy scar. Because these lesions are very thin and contain only a relatively scanty cancer component, usually surrounded by a dense fibrous stroma, sampling can be difficult. A very thin needle is usually best suited for the aspiration procedure, with 26- or 27-gauge needles being optimal. To complicate matters further, the skin is highly sensitive and sampling can be quite painful. Local anesthesia applied to the area of the lesion is effective.

The **position of the needle should be almost parallel to the skin surface**. The needle tip should be inserted at the edge of the target and the needle moved back and forth through it, remaining within the thickened skin (Fig. 28-18). If the needle is inserted at a 90° angle to the skin, it inevitably will slip through the target into the subcutaneous tissue, resulting in a sample containing only fat.

Large Lesions

Necrosis generally occurs in the center of large lesions because of an inadequate blood supply. Therefore, if the first sample yields only necrotic debris, another sample, obtained tangentially to the edge of the mass, should be secured. This strategy is also helpful when the initial sampling yields squamous debris or mature squamous cells, which may represent metastatic squamous carcinoma. Still, a careful microscopic examination of the necrotic debris may yield valuable information in many cancers and in infectious processes such as tuberculosis.

P.1071

Figure 28-18 Needle aspiration of intracutaneous lesions. Use a 26-gauge or smaller needle. The needle should be placed tangentially in order to avoid penetration of the subcutaneous fat.

Masses in the Axilla

Axillary masses are difficult to aspirate, especially if they are situated high in the axilla and are movable and small. They are usually best palpated with the patient in an upright position with the arm relaxed and only slightly abducted (Fig. 28-19). The index and middle fingers are used to reach above the mass, press it against the chest wall, and pull it down, if possible, into a position more accessible to sampling. With the mass held firmly in this manner, the thumb of the same hand should be placed below the mass to further immobilize it and facilitate the aspiration. The operator should sit somewhat lower than the patient, facing the axillary area. An assistant may support the patient's arm, or the patient may place his or her hand on the operator's shoulder and let the arm hang as relaxed as possible. **If the mass is palpable and accessible while the patient is lying down, sampling may be done in this position.**

Figure 28-19 Needle aspiration of deeply seated axillary lesions. With the patient in the sitting position, allow the arm to hang relaxed. With the forefinger and middle finger, pull the lesion down against the chest wall. Smooth out the fat tissue with the thumb. The needle should be tangential to the chest wall.

Lesions of Bone and Deep-Seated Soft-Tissue Masses

A careful review of radiologic studies is necessary before attempting aspiration of **lesions involving bone**. Such lesions can be sampled easily by aspiration, provided that the cortex has been markedly thinned or eroded. If a thick layer of cortical bone covers the target, access may be gained by using various trocar-type instruments designed for this purpose.

Soft-tissue masses are suitable targets for aspiration. However, it has been my experience that frequently the mass is deeper than it appears to be on initial clinical examination. Three-inch spinal needles are often useful in these situations. Occasionally, CT guidance is helpful even when the mass is clinically apparent. For further comments on aspirates of bone and soft tissue, see Chapters 35 and 36.

P.1072

See Chapter 33 for lesions of the prostate, and Chapter 41 for lesions of the eye.

FAILURE TO OBTAIN A REPRESENTATIVE SAMPLE: WHY IT OCCURS AND HOW TO CORRECT IT

Excessive Blood

A specimen diluted with a substantial amount of blood is likely to be inadequate for diagnosis. There are several ways to reduce the amount of blood. The first sampling of an area is the most likely to yield a good specimen, and it should be carefully planned. In subsequent samples

the amount of blood is likely to increase substantially. If the mass is 1.5 cm or larger in diameter, one should consider sampling two or more areas. In this way, it is often possible to obtain two optimal samples. Bleeding is reduced if the direction of the needle is not changed when the tip is inside the target (see Basic Aspiration Technique section above).

As discussed above, when sampling highly vascular organs, such as the **thyroid gland**, it may be impossible to avoid aspirating substantial amounts of blood in spite of good technique. The procedures to follow in aspiration of the thyroid are discussed above. The sampling technique without suction, also described above, is often effective in targets with an abundant blood supply. For samples containing a substantial amount of blood, special smearing techniques designed to concentrate the tissue fragments can be used (see above).

Insufficient or Nonrepresentative Material

Insufficient material may result from one of several causes, including **incorrect needle placement**. For instance, if the needle is placed at a 45° angle overlying a 1-cm mass situated 0.5 cm under the skin surface, the needle tip will not enter the mass (Fig. 28-20). When choosing an angle other than 90°, the needle tip must be placed in a manner that will allow it to penetrate the lesion. Other common examples of incorrect needle placement include **inserting the needle tip too deeply or too superficially**. Sometimes, especially in the breast, a mass may seem to be deceptively large. For example, a mass may appear to be 3 cm in diameter on palpation; however, not infrequently, the solid core of the neoplasm will be less than half that size. In order to acquire a good specimen, the needle tip must be placed within that core (Fig. 28-21). In this situation, it is often very helpful to use the needle tip as a sensitive indicator of changes in consistency. When the needle enters an area of increased resistance, it is likely that the tip is correctly positioned for sampling. **Insufficient sampling also occurs when the target is not completely immobilized** and the target is moving back and forth with the needle tip. To prevent this, firm pressure must be used, and the fingers holding the target should be very close to it (see Figs. 28-5 and 28-6). This is especially important with small targets measuring 1 to 2 cm in diameter.

Figure 28-20 Placement of the needle depends on the angle used. The use of the wrong angle may result in a missed target.

Figure 28-21 A 1-cm central core containing the diagnostic material in a palpable mass measuring 3 cm clinically.

A **target composed predominantly of dense connective tissue stroma** may also present a sampling problem. In this case, as the needle penetrates the target, the consistency of the target resembles that of rubber. It is often difficult to make a 22- or 23-gauge needle travel back and forth through such a target. These targets often contain a relatively scant epithelial component, and frequently yield a “dry tap” or a very scanty cell harvest. Fibrocystic change in the breast is an example of a lesion that can have these characteristics, but breast cancers, especially of the invasive lobular or scirrhous type, can be very similar. As indicated above, smaller (25-gauge) needles will penetrate the dense fibrous tissue more easily. In the case of invasive lobular carcinoma, the center of the mass may be almost acellular. However, the periphery of the mass is usually richer in cells, making it possible to harvest diagnostic material.

Air-drying artifacts occur when alcohol fixation is delayed, even for a few seconds. Specimens with scanty cellularity are especially sensitive to drying. To avoid air-drying, the container with the fixative should be at hand, **open** and ready to use. The decision as to whether to fix a smear in alcohol should be made before the smear preparation has been completed. **The inspection of the slide should be delayed until after initial brief fixation.** If spray fixatives are preferred, an assistant should be ready to apply the fixative as soon as the smear preparation has been completed (for description of fixatives, see Chap. 44).

Blood clotting is a common problem. It distorts the architecture of cell clusters and may obscure microscopic

P.1073

detail. To avoid clotting, the aspiration procedure must be fairly rapid. This requires practice in sampling and smear preparation techniques to the point where the motions follow each other naturally and there is no need to hesitate and recall what should be done next (see Model for Learning the Basic Sampling and Smearing Technique section below). When clotting occurs during smear preparation, alcohol fixation is generally preferable to air-drying because it allows better visualization of the cells in the sample.

Crush artifact is another problem that usually has one of two causes. Crushing occurs when too much pressure is applied to the material during smear preparation. Crushing also occurs if the smear preparation technique, performed with two slides, is faulty and the slides form a slight

angle during smearing instead of being parallel (flush) with each other. The result is scraping rather than smearing of the harvest (see Fig. 28-11). Crush artifact may also occur if the sliding movement begins with the slides parallel to each other, but the top slide is angled before the smear is completed. This results in a satisfactory smear at the top end of the slide, but crushed cells and decreased cellularity at the bottom. This artifact is usually apparent when the smear is inspected with the unaided eye.

If single cells and clusters of cells overlap to the extent that they interfere with interpretation, insufficient pressure may have been applied during smearing. This is a much less common problem than excessive pressure. Difficulty in separating fluid from tissue fragments occurs when the two-step technique is used and the bottom slide is insufficiently tilted toward the frosted end. This tilt must be maintained throughout the procedure.

MODEL FOR LEARNING THE BASIC SAMPLING AND SMEARING TECHNIQUE

Fresh animal livers, available in food stores, can serve as a safe and useful tool for learning the basics of both sampling and smear preparation. **Beef and pork livers** are preferable to chicken livers because there is less likelihood of air pockets **and plugging of the needle by fibrofatty tissue**. A simple model can be prepared by placing a quarter-pound piece of liver into a single or double latex glove, which is then tied off. Since no real aspiration targets are present in this model, lesions of different sizes and at different depths will have to be imagined. It is often helpful to outline the size of a target on the glove with a marker or pen. Important things to consider during the practice sessions include proper placement of the nondominant hand to stabilize the “target,” the location of the needle tip during sampling, and the number of needle excursions.

As far as smear preparation is concerned, the liver is a suitable practice material because it has properties very similar to those of many cancerous tissues. The aspirated sample is suitable for the one-step smear technique and for dividing material for multiple smears. For practice in handling diluted material, a few drops of tap water can be mixed with the tissue fragments on the slide after they are expelled from the needle. Experience can also be gained by **sampling fresh tissues from surgical pathology procedures**. An added bonus is the acquisition of histologic reference materials from various lesions.

Common problems that can be corrected with this model include a tendency for the needle to penetrate somewhat deeper with each excursion so that the tip ends up beyond the target. Another problem is the lateral pressure on the instrument, which can be identified by wrinkling of the glove surface and slight bending of the needle. Lateral pressure is hazardous to the operator because if the needle accidentally slips out of the patient, it may stick one of the fingers holding down the target. This is especially dangerous when dealing with patients who are carriers of hepatitis or human immunodeficiency virus (HIV).

Performing actual aspiration biopsies and preparing smears of the resulting harvest from living patients is more demanding than working with animal livers. The patient requires considerable attention, and once sampling is under way, time is of the essence.

To become skilled at sampling and smearing, it is necessary to perform many biopsies on patients. However, the process can be accelerated considerably by conducting repeated practice sessions with animal livers before attempting the procedure in a clinical setting.

APPROACH TO THE INTERPRETATION OF THE ASPIRATED SAMPLE

Several factors are important in the interpretation of the aspirated sample:

- **Accurate knowledge of clinical data**

- Sex and age
- Clinical signs and symptoms
- Anatomic location of the lesions
- Relationship of the lesion to adjacent structures and organs (i.e., is the lesion freely movable or attached?)
- Roentgenologic or ultrasound findings
- Laboratory data (these data must be obtained either directly from the patient or from clinical colleagues)

- **Gross appearance of the sample**

- Cystic lesions will yield fluid in various amounts and of variable color and levels of turbidity.
- Solid lesions will yield only material contained in the needle and the tip of the syringe. As the material is expressed on the slide, the **color** of the first droplet may be significant; malignant tumors or other cellular lesions will often appear as **granular, grayish material**. A **bloody appearance** of the droplet may indicate dilution with blood. The **consistency** of the droplet may also vary: thyroid lesions rich in colloid, or lesions rich in mucus may yield glue-like, viscous material.

Low-Power Review

As the first step in assessing the smears by low-power viewing, it is important to answer the following questions:

P.1074

- Does the smear contain cellular material other than blood?
- Is the smear rich in cells?
- Are the cells lying singly or in clusters? (If clusters are present, their general configuration is of value, as discussed elsewhere in this book.)

High-Power Review

In smears that are judged satisfactory after preliminary viewing, a high-power examination is required to establish the definitive diagnosis.

TRANSLATING CYTOLOGIC PATTERNS INTO HISTOLOGIC PATTERNS

For a pathologist, a cardinal step in the mastery of aspiration cytology is the ability to translate the cytologic patterns into histologic tissue patterns of diagnostic value. A cytologic preparation obtained by aspiration may be compared with a jumbled puzzle in which the components must be fitted together by the observer to form a familiar picture. Furthermore, a histologic section has an essentially flat, two-dimensional quality, and represents a thin cross section of a tissue or organ. The cytologic preparation from an aspirated sample is often three-dimensional, as it usually contains structured fragments of tissues that were removed in toto from their setting and subsequently squashed between the slide and the coverslip. Single detached cells usually accompany the tissue fragments. The mere quantitative relationship between the tissue fragments or clusters and single detached cells is in itself a source of important information. In

general, a cytologic pattern requires **synthesis** of the evidence, whereas a histologic section requires **analysis** of the evidence.

A common property of cancer cells is their poor adhesiveness (see Chap. 7). Consequently, **aspirates of malignant tumors often contain large populations of cancer cells selectively removed from the target**. Thus, rich cellularity of smears and cell dispersion are the hallmarks of cancer. **Aspirates of benign targets** are usually less cellular and contain fewer single cells. Still, there are numerous exceptions to the rules; hence, a careful examination of the entire evidence is required. In general, it is advisable to study not only the make-up of the cell clusters but also the individual detached cells before a diagnostic conclusion is reached. The understanding of the messages contained in cell clusters and single cells is discussed at some length below.

The diversity of organ sites that can be aspirated places severe demands on the interpreter of the cell samples. A great variety of microscopic patterns must be mastered to differentiate the normal from the abnormal, and to classify the abnormal according to diagnostic categories of clinical value. Thus, **basic training and experience in histology and surgical pathology are essential prerequisites** that must be met before aspiration cytology is attempted.

Benign Tissues

Ducts and Acini

Tissues that contain ducts and glands, such as the breast, the prostate, the salivary glands, and the pancreas, are among the targets most often aspirated. The principal characteristics of benign ducts and acini in aspirates are summarized in Figure 28-22A,B. The following features must be emphasized:

- There is a generally good adherence of cells, forming flat sheets or clusters.
- The cell borders are well demarcated, with formation of the “honeycomb” pattern, often accompanied by evenly distributed, centrally located nuclei.
- The nuclei are of uniform size, with fine chromatic structure and absence of molding.
- The nucleoli are absent or small.
- Myoepithelial cells in the form of small, dark, oval nuclei, within and outside of clusters, are often present. When occurring singly, the myoepithelial cells are typically seen as bare nuclei devoid of cytoplasm.

Multilayered Epithelia

The principal characteristics of aspirated multilayered epithelia are shown in Figure 28-22C.

Squamous epithelium or the urothelium (transitional epithelium), when aspirated, shed well-demarcated cells, either singly or in small clusters. The following features must be emphasized:

- The cells vary in size, depending on their derivation (cells from superficial layers are generally larger and have a more abundant cytoplasm than cells from deeper layers).
- The nuclei are uniform in size and have finely granular chromatin. Nucleoli are generally not visible.

Note that the nuclei of superficial squamous cells tend to be pyknotic. Superficial urothelial cells (umbrella cells) are often multinucleated, and the individual nuclei may be large and contain

nucleoli (see Chap. 22).

Connective Tissue

As Figure 28-22D indicates, the spindly cells of aspirated connective tissue typically appear as single cells or compact, multilayered clusters. The nuclei of fibroblasts are generally oval and may contain small nucleoli. The cytoplasm is delicate. Fragments of connective tissue with fibroblasts bound by collagen may be observed in some situations. In general, the amount of connective tissue stroma is scanty, but there are some exceptions to this rule.

Capillaries and Other Small Vessels

In aspirates, the capillaries (as shown in Fig. 28-22E) appear as three-dimensional, sausage-like, elongated tubular structures,

P.1075

measuring 10 to 30 μm in diameter and filled with blood cells. Under some circumstances, branching capillaries with a mantle of fibroblasts may be observed.

Figure 28-22 Comparison of histologic patterns with cytologic patterns in aspirates of some benign tissues. *A. Acini.* *Left,* Schematic presentation of a cross section of a gland acinus with myoepithelial cells surrounding glandular cells. *Right,* In smears whole acini appear as sharply outlined, cohesive, multilayered clusters of cells of even sizes. The myoepithelial cells (MEC) may either be found within the squashed acini or appear as dispersed, comma-shaped, dark nuclei outside of the cell clusters. Fragments of acini appear as small cell clusters with sharply demarcated cell borders forming a honeycomb pattern. The myoepithelial cells are seen either outside or within these cell clusters. *B. Ducts.* *Left,* Schematic presentation of a cross section of a duct with MEC. *Right,* In smears the ducts appear as flat epithelial structures in a honeycomb pattern or as detached fragments in which the cells are arrayed in parallel rows. Depending on the

caliber of the duct, the cells are either cuboidal or columnar in shape. The MEC are seen either within or outside of cell clusters. *C. Multilayered epithelium. Left, Schematic presentation of histology. Right, The presentation in smears depends on the type of epithelium. The cells may either form cohesive clusters or appear singly. The size of the individual cells depends on the level of the epithelial maturation. Superficial squamous or urothelial cells are significantly larger than cells from the deeper layers. D. Connective tissue. Left, Schematic presentation of fibroblasts in a tissue section. Right, In smears, detached fibroblasts may either appear singly or form loosely-structured clusters. Smooth muscle has a similar presentation. E. Capillaries. Left, Schematic presentation of a cross section of a capillary with blood cells in the center. Right, In smears the capillaries in aspirates appear as tubular structures crowded with blood cells.*

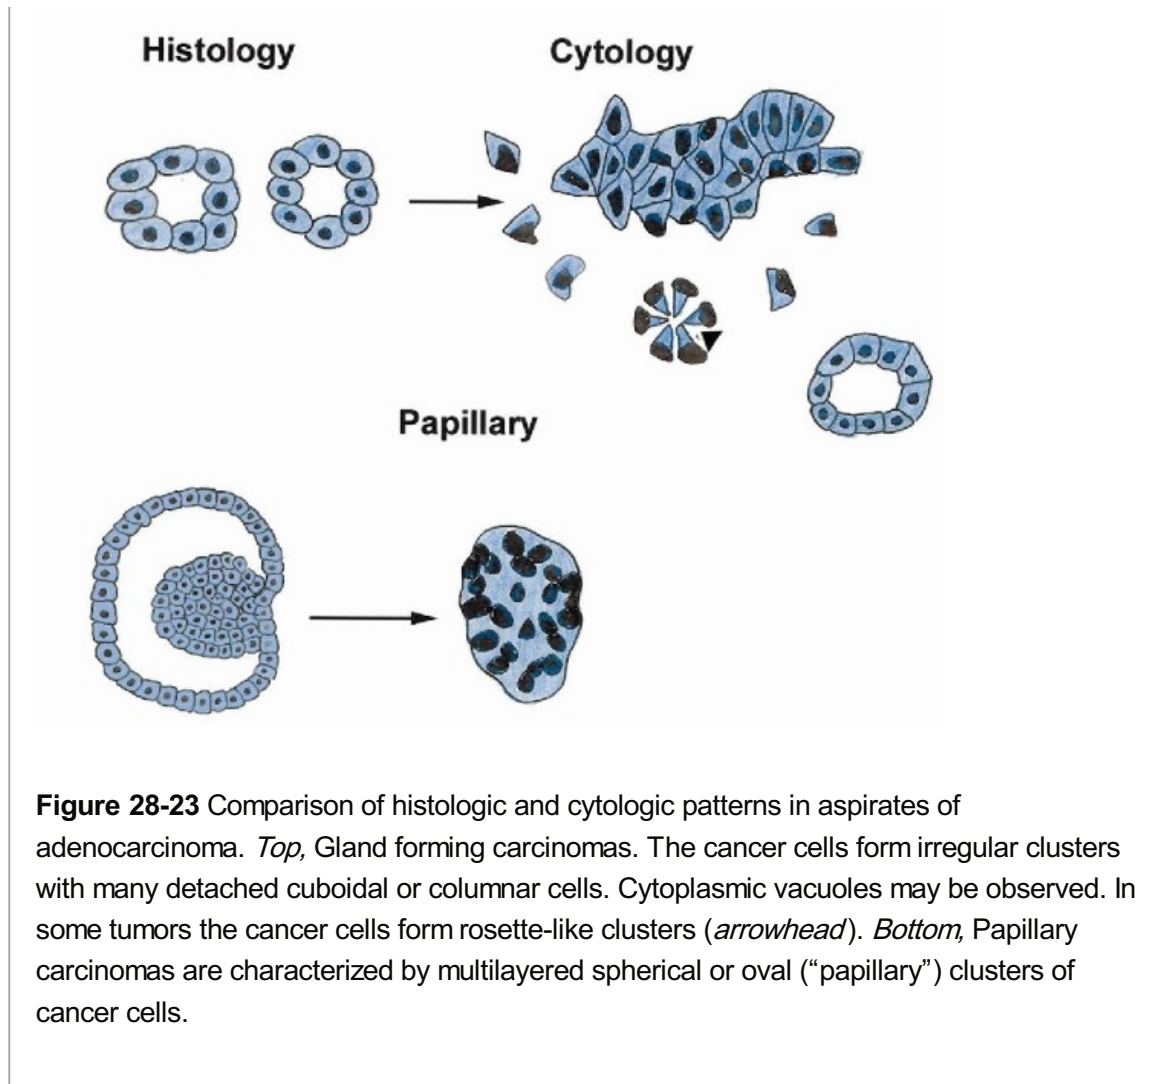

Malignant Tumors

Adenocarcinomas

Figure 28-23A,B summarize the principal cytologic features of adenocarcinomas. The presentation depends on the degree of differentiation, but in general, adenocarcinomas share certain common characteristics:

- There is formation of large, three-dimensional cell clusters composed of several layers of superimposed cells. Monolayered clusters (sheets of cells) may also occur in well-differentiated tumors.
- In papillary adenocarcinomas, the clusters tend to be spherical or oval, and may show palisading of peripheral cells.
- Individual tumor cells, which are almost invariably present, may have a cuboidal or columnar configuration, with clear or vacuolated cytoplasm.
- The nuclei, enlarged to various degrees, may show only moderate hyperchromasia and a moderately coarse arrangement of chromatin. Distortions of nuclear shape may be observed. Large, sometimes multiple, nucleoli are common.
- **Products of cell secretion** include intra- or extracellular mucus and large intracytoplasmic vacuoles. **Psammoma bodies** or concentric proteinaceous structures that are commonly calcified may be observed in a variety of papillary carcinomas.

P.1076

Solid Carcinomas

The main cytologic features of solidly growing carcinomas are shown in Figure 28-24. The following must be emphasized:

- Cancer cells are more likely to appear singly than in clusters.
- The cell clusters have no particular structural arrangement and may be mono- or multilayered.
- The individual cells are of variable shape and configuration, and in squamous carcinomas may be very bizarre.
- In some tumors, notably the epidermoid and urothelial cancers, the cytoplasm of individual cells is sharply demarcated. In squamous carcinoma, the cytoplasm may show marked eosinophilia suggestive of keratin formation. The keratin formation may be sufficiently abundant to change the affected cells into an anucleated squame or a “ghost cell.” In other tumors, the cell borders are often indistinct, and in clusters cannot be identified.
- The nuclei are markedly enlarged and hyperchromatic, and have a very coarse chromatin pattern. Nuclear molding is common. Large nucleoli may be present, particularly in poorly differentiated cancer cells.

Figure 28-24 Comparison of histologic and cytologic patterns in aspirates of solid carcinomas composed of large cells. The cancer cells are either dispersed or form small clusters. This tumor type is usually easily identified in smears.

P.1077

Anaplastic (Poorly Differentiated) Carcinomas

The principal features of anaplastic carcinomas (shown in Fig. 28-25) are as follows:

- Cancer cells may range in size from very large to very small, depending on the tumor type.
- Most cancer cells are dispersed, but small-cell clusters are nearly always present.
- The cytoplasm of the tumor cells is often poorly preserved and appears scanty.
- In small-cell-type carcinomas (oat-cell carcinomas), there are nearly always **two types of nuclei**: larger, better preserved **vesicular nuclei**, and small **pyknotic nuclei**.
- The nuclei are nearly always hyperchromatic.
- In small-cell carcinomas, the cells in clusters show molding. This feature is helpful in separating anaplastic carcinomas from lymphomas.
- The nucleoli are usually not prominent.
- The tumor cells are very fragile, particularly in small-cell carcinomas, and are often destroyed during smear preparation, forming a **“crushing artifact”** or streaks of DNA.

Malignant Lymphomas

The cytologic features of malignant lymphomas are described in Chapter 31. The key features of lymphomas are the scarcity of cell clusters, the absence of nuclear molding, and the presence of lymphoglandular bodies (see Chap. 31).

Soft-Tissue Sarcomas

The great variability of configuration of soft-tissue sarcomas precludes any generalization in reference to their cell patterns. In general, spindle-cell sarcomas will display elongated cells, singly and in jumbled clusters. The nuclear features are quite variable and not necessarily indicative of tumor prognosis.

Other forms of sarcomas may display some characteristic features, such as osteoid formation in osteosarcomas, fat in liposarcomas, and cross-striations in rhabdomyosarcomas. Pigment formation in malignant melanomas and related tumors is diagnostically very helpful, if present.

ORGANIZATION OF AN ASPIRATION SERVICE

Performance of the Aspiration

The needle aspiration technique for palpable lesions originated with clinicians in the United States and Europe. However, two different pathways of interpretation emerged. Initially, in the United States the smears, obtained by clinicians or radiologists, were usually interpreted by pathologists. In Sweden and other European countries, however, they were interpreted by the same person who performed the aspiration, perhaps because in the past, no pathologists were available to perform this service (Koss, 1980b; Söderström, 1980). Both pathways offer certain advantages. A careful clinical history and first-hand knowledge of the palpable findings may assist in the interpretation of the aspirated sample. If the person performing the aspiration is a clinician, he or she is at the mercy of the histopathologist who interprets the tissue patterns. The interpretation of the cell sample by pathologists offers the benefit of comparison of the cell and tissue patterns, but often deprives the pathologist of the benefit of detailed clinical findings.

The current trend among pathologists is to combine all three functions: performing the

aspiration of palpable lesions, and interpreting the cell sample and the tissue. Fellowships in cytopathology, which are offered by many institutions in the United States, train young pathologists in both the aspiration technique and smear interpretation. However, with the introduction of aspiration biopsy of nonpalpable lesions requiring roentgenologic or ultrasound guidance for precise targeting, the radiologists, other ultrasound specialists, and, in some instances, gastroenterologists

P.1078

and specialists in nuclear medicine have remained active participants in the aspiration procedures.

The Aspiration Clinic

Many institutions have now organized an aspiration clinic run either by cytopathologists who perform the procedure and interpret the material, or by a team consisting of radiologists, physicians, or surgeons who perform the aspiration, and a cytopathologist who interprets it. Such aspiration clinics offer the benefit of a centralized outpatient area that may be equipped with appropriate examination tables and equipment required for a variety of aspiration procedures. A small laboratory facility with appropriate stains and a microscope is also available for testing the adequacy of the samples and, at least in some cases, for an immediate diagnosis. The aspirated material is referred to the central laboratory for further processing. In most instances, patients with palpable lesions require only a short recuperation period before being sent home. The final diagnosis is available to the referring physician or surgeon (and the patient) sometimes within minutes, but usually within 2 to 3 hours after aspiration. In hospitals, in order to make the aspiration procedure available at all times on very short notice (not unlike a frozen section), it is advisable to designate a person as being "on call" and to provide this person with appropriate equipment.

The system implemented at Montefiore Medical Center consists of a cart containing slides, bottles with fixatives, rapid stains, an assortment of necessary instruments, and a microscope. The cart is manned by a cytopathology staff member or fellow, or a pathology resident who is on call from 8 a.m. to 5 p.m., the customary hours during which aspirations are performed. **It is the duty of the person in charge** to obtain the essential clinical and roentgenologic data that may prove important in the interpretation of the material, to pass preliminary judgment on the adequacy of the aspirated sample, and to prepare the material for final processing and interpretation. This system has proven to be effective over a period of 15 years.

29

The Breast

Cancer of the breast is the most important malignant disease affecting **women** in the industrialized world. It is the **principal cause of cancer morbidity and mortality** in the United States, with 192,200 new cases and 40,200 deaths estimated for the year 2001 (Greenlee et al, 2001). The most important **risk factor** is a history of breast cancer in close relatives. A small number of patients come from families that have mutations of the **breast cancer genes BRCA1 and BRCA2**, and perhaps other genes as well (Lakhani et al, 1998; Loman et al, 1998, 2000; Haber, 2000; Hedenfalk et al, 2001; Ziv et al, 2001). The risk of breast cancer is minimally increased in women who take **hormonal contraceptives**, but this risk is no longer present 10 years after cessation of medication (Collaborative Group on Hormonal

P.1082

Factors in Breast Cancer, 1996). However, treatment with estrogen and progestin for symptoms of menopause constitute an important risk factor, regardless of whether the treatment is of short or long duration (Chlebowski et al, 2003; Li et al, 2003b). Heritability of **mammographic densities** has also been tentatively suggested as a risk factor (Boyd et al, 2002).

Breast cancer has a well known and much studied **natural history**. The morphologically recognizable initial stages of breast cancer are **carcinomas in situ** that are confined to breast ducts or lobules, or both. It is evident that a major upheaval in cell proliferation genes, such as p53, must occur before the tumor develops, but very little is known about these early events (Haber, 2000). **Invasive breast cancer is derived from carcinoma in situ**; however, the precise rate of progression is unknown. Once invasion has occurred, breast cancer can metastasize to regional axillary lymph nodes and beyond.

Staging reflects the extent of the spread of **breast cancer**. According to the TNM (*tumor, lymph nodes, metastases*) classification system, carcinomas in situ are classified as **Tis**; tumors that are limited to the breast and are no larger than 2 cm in diameter are **T1**; larger tumors limited to the breast are **T2** or **T3**, and tumors with evidence of metastatic spread are **T4** (Rosen, 2001). The concept of **sentinel lymph node (SLN)**, i.e., the **axillary lymph node most likely to harbor metastatic cancer, as identified by tracing substances** (a blue dye or radioactive colloid, or both, injected into the breast), has become important in assessing treatment options (Giuliano et al, 1994, 1995; Fraile et al, 2000; McMasters et al, 2000). An SLN containing metastatic cancer documents that the disease has spread beyond the breast into the homolateral axillary lymph nodes.

The behavior and prognosis of breast cancer are generally **stage related**. Early-stage cancer that is limited to the breast has a better prognosis than cancer that has spread to the lymph nodes. However, for reasons that are not well understood, **the behavior is unpredictable in many instances** (Li et al, 2003). Some early-stage, low-grade carcinomas may progress rapidly, and, vice versa, patients with metastatic cancer at discovery may have

excellent long-term survival. Possible factors in the prognosis of breast cancer are discussed further on in this chapter.

Prior to the 1980s, the principal mode of diagnosis of breast cancer was the appearance of a palpable **breast lump**, discovered by either the physician or the woman herself. With the introduction of **mammography and ultrasonography**, and the recognition that nonpalpable cancer of the breast may be identified by these diagnostic modalities, it has become a mantra in medical practice that early diagnosis of mammary carcinoma offers women a choice of therapeutic options and the best chance for cancer-free survival (Fisher, 1999). The value of mammography as a screening mode for breast cancer detection has been brought into question by a metaanalysis of the results of several clinical trials (Gotzsche and Olsen, 2000; Olsen and Gotzsche, 2001). A significant controversy over this issue has resulted from these studies. A more recent analysis from Sweden reported that mammography reduced mortality from breast cancer by 21% (Nyström et al, 2002). A study in Finland indicated that the prognosis of breast cancer discovered by screening mammography is better than that of lesions of similar size discovered by palpation (Joensuu et al, 2004). **Magnetic resonance imaging (MRI)** of the breast has been recommended as the optimum mode of breast cancer detection in women with mutations of breast cancer genes 1 and 2 (Warner et al, 2004).

There is good evidence that for women with small breast cancers (less than 3 cm in diameter), the survival options have increased significantly with the use of various forms of adjuvant therapy, such as radiotherapy, after local excision of the tumor (**lumpectomy**) and chemotherapy, administered either before or after surgery (National Institutes of Health, 2000). Prophylactic mastectomy has been shown to be of value in very high risk women (Meijers-Heijboer et al, 2001; Ghosh and Hartmann, 2002; Ryan et al, 2003).

The failure to establish a diagnosis of breast cancer in a timely fashion may result in dire consequences for the patient and the physician. Dedicated breast cancer centers have been created to provide women with reassurance if no disease is found, and with early diagnosis and treatment if breast cancer is suspected. **Breast cancer in males is uncommon** and is not a public health problem. Regardless of the sex of the patient and the method used to discover the lesions, **cytologic techniques play an important role in the diagnosis of mammary carcinoma**.

METHODS OF INVESTIGATION OF THE BREAST

The breast may be subjected to self-examination or to palpation by a health provider, resulting in the discovery of a breast "lump." **Mammography** serves to reveal nonpalpable **abnormal densities**. **Especially suspicious are those with ragged borders or clusters of microcalcifications**, both of which require further diagnostic clarification. **Ultrasonography** may also be used for tumor detection, and is particularly helpful in separating **solid from cystic lesions**. **Magnetic resonance imaging (MRI)** has been shown to be an effective technique for the detection of breast cancer, although it has a lower specificity than mammography (Weinreb and Newstead, 1995).

The **stereotactic technique** of needle aspiration of nonpalpable lesions detected by mammography was first developed at the Karolinska Hospital in Stockholm (Bolmgren et al, 1977). The initial procedure was quite complex and required taking three films of the breast, using a special table with the breast positioned in an aperture in the table top and compressed to facilitate imaging. The position of the lesion was calculated by means of a computer. A cannula (1 mm thick, with an internal stainless steel needle) was inserted into the mammary

tissue and cellular material obtained, as described in Chapter 28. After the sampling was performed, a small stainless steel suture was threaded into the lesion, and the path between the lesion and the skin was marked by injection of India ink to serve as a **marker for surgical removal of the lesion, if warranted**. Since these early efforts, new machines for stereotactic aspiration

P.1083

of small, mammographically-detected breast lesions have become available, but the fundamental principles have remained the same. Within recent years, **ultrasound techniques** have been used for the same purpose. None of these methods guarantees the discovery of all breast lesions (Kerlikowske et al, 1995). Helvie et al (1991) pointed out that about 7% of women undergoing guided-needle biopsies or wire-localization procedures suffer from a **vasovagal reaction**, which in some cases may be severe and require treatment.

Current practice requires that **any lesion that is considered even remotely suspicious on clinical examination, mammography, sonography, or MRI** should be examined microscopically to avoid missing a cancer. The rate of **falsepositive screening mammograms** in women between the ages of 40 and 69 has been estimated at 23.8% on multiple screenings, and at 13.4% on clinical examination with a colossal cumulative **false-positive result of 49.1% after 10 annual examinations** (Elmore et al, 1998). Consequently, a large proportion of breast biopsies are negative for tumor. There are several competing approaches to breast biopsy:

- **Surgical excisional biopsy**
- **Core needle biopsy**
- **Biopsy by aspiration or fine-needle aspiration (FNA)**

The selection of the optimal method of biopsy depends greatly on the clinical circumstances, the mammographic or ultrasound findings, the skill of the operator, and the confidence of the physician or surgeon performing the cytopathological examination. Of the three approaches, the **excisional biopsy is the most traumatic and expensive, but it offers the best diagnostic material**, particularly for proving the absence of a malignant tumor. Excisional biopsy of very small lesions may cause significant problems for localization, unless a marker guiding the surgeon is placed in the breast during a visualization procedure (see above). If the excised lesion is histologically benign, the scar tissue will tend to make subsequent mammographic checks more difficult.

The core needle biopsy, which may be performed under ultrasound guidance, is less traumatic but **it may miss the critical lesions, and**, in the case of doubt, may still have to be followed by an excisional biopsy (Parker et al, 1993). All tissue biopsies require fixation, embedding in paraffin, and cutting and staining of sections, and therefore are **expensive and time-consuming**.

Needle Aspiration Biopsy (FNA)

As discussed in Chapter 28, FNA can be performed with only a needle (Zajdela et al, 1987) or with a needle, syringe, and reusable syringe holder. It does not require elaborate tissue processing and is therefore the **least expensive method of diagnosis** (Layfield et al, 1993). The **savings** per 1,000 FNAs, in comparison with surgical biopsies, have been calculated at \$250,000 to \$750,000 (U.S.) (Rimm et al, 1997). An FNA **does not require anesthesia or hospitalization, and it takes only a few minutes to perform. It is therefore the most**

rapid and most versatile of the three approaches. A preliminary judgement as to the adequacy of the sample, and in many instances the diagnosis, can be made within minutes, thus alleviating the anxiety that any woman inevitably experiences when informed that she has a mammary lesion. A rapid diagnosis of a malignant tumor may also allow the patient to participate in the choice of therapies, some of which lead to preservation of the breast [i.e., local or segmental resection (**lumpectomy**)], followed by radiotherapy and chemotherapy. In many instances these treatments can replace a mastectomy, with equivalent results. Thus, **FNA may save anxiety, trauma, time, and money**. FNA is particularly valuable **when the level of clinical suspicion is low**, either because of the type of abnormality involved or the young age of the patient. Under these circumstances, the odds that the lesion will be benign are very high, and thus the health care provider may be hesitant to recommend a traumatic and costly tissue biopsy. The availability of a competent FNA team may provide an important diagnostic option. Dawson et al (1998) reported excellent results in breast cancer diagnosis in women age 35 or younger. Cohen et al (1987) and Ljung et al (2001) emphasized that **expertise in the procurement of the FNA sample** is as important as sample interpretation in achieving the correct diagnosis in 97% to 98% of patients.

Aspiration biopsy (FNA) of mammary lesions has become a quasi-routine clinical procedure in many hospitals and clinics, often replacing a preoperative tissue biopsy. The procedure may be used in the diagnosis of **palpable lesions** that may be either **solid or cystic**, or **nonpalpable lesions** detected by mammography, ultrasonography, or MRI. At the time of this writing, tiny lesions (measuring 3 to 5 mm in diameter) can be detected by these techniques and can be sampled by surgical excision, a core biopsy, or aspiration cytology.

For the best results, **palpable breast lesions** should be aspirated by a skilled, trained pathologist who can obtain the patient's history directly from the patient. Sanchez and Stahl (1996) suggested that **asking the patient to indicate the location of the lesion is more reliable than actual palpation**, which may require the use of soap or cream to localize small lesions. The actual aspiration procedure is described in Chapter 28. It is the consensus of most observers that in most cases, **two to four passes of the needle** are required to harvest optimal diagnostic material (Pennes et al, 1990). Aspiration biopsy has also been shown to be useful **after segmental resection** because it allows the separation of benign sequelae of the procedure from recurrent carcinoma (Ku et al, 1994).

Smears or cell block material from patients with breast cancer are also suitable for **ancillary examinations** of possible prognostic value, such as **quantitation of steroid receptor-binding** [estrogen (ER) and progesterone (PR)], **proliferation antigen** (e.g., Ki 67), and **DNA ploidy analysis and detection of gene expression** (e.g., HER-2; see below).

Although FNA is the most **cost-effective approach** to the diagnosis of **palpable breast lesions**, as discussed above, the **procedure does involve certain diagnostic failures**, as discussed below and again under Results. Obviously, "total reliability" in diagnosing breast cancer cannot be achieved

P.1084

with any approach. The issue should be openly discussed with women who are led to believe that breast cancer is always diagnosable, and that a failure to do so is a punishable offense that belongs in a court of law (Koss, 1993).

Limitation of the Aspiration Biopsy

Given an adequate sample and an experienced interpreter, FNA is **highly reliable for the**

diagnosis of cancer. If, however, **the FNA is judged to be “atypical” or “suspicious,” the procedure should be repeated, another opinion should be sought, or the lesion should be excised for histologic examination.** Breast aspiration is a serious responsibility for the pathologist, and a false-positive diagnosis may result in an unnecessary mutilation of the patient, not considering the legal consequences. Whatever caveats have been expressed in this regard in the preceding chapters, they must be repeated and reinforced again in reference to the breast. **Once breast tissue is removed, it cannot be replaced.**

If the smear is considered **negative for tumor**, lingering doubts may remain as to whether the sample was **representative of the aspirated lesion and was appropriately interpreted.** In such cases, the **“triple test”** may be of help. The triple test consists of a **comparison of the clinical and mammographic findings with the results of the FNA** (Hahn et al, 1980; Hermansen et al, 1987; Kaufman et al, 1994; Vetto et al, 1995; Morris et al, 1998; Salami et al, 1999). If all three are negative for tumor, the reliability of negative cytologic findings approaches 100%; however, missed diagnoses can occur occasionally, even with several passes of the aspiration needle. Perhaps for this reason, at the time of this writing (2004), **core tissue biopsies are preferred to needle aspiration biopsies by some physicians when the lesion is diffuse and likely to be benign.** Still, core biopsies may also fail, as discussed below under Results.

A proposed **protocol for patient management**, which includes the triple test, was established during the consensus conference sponsored by the National Cancer Institute (1997) (Diagram 29-1).

Aspiration biopsies may sometimes **impact subsequent tissue biopsies.** Lee et al (1994) observed hemosiderosis, hemorrhage, and, rarely, partial necrosis of breast tissue in 17 of 184 patients.

Intraoperative Cytology

Intraoperative cytology, which is briefly described in Chapter 1, may add to or, in some cases, replace a frozen section. Touch or scrape smears are easy to interpret in cases of obvious cancer, but may cause problems if the lesion is difficult to interpret (Esteban et al, 1987; Oneson et al, 1989; Silverberg, 1995). The technique has been applied to **sentinel lymph nodes** (Viale et al, 1999; Llatjos et al, 2002). Sauer et al (2003) reported that **imprint cytology** of sentinel lymph nodes is rapid and reliable, provided that the screening is done by experienced personnel.

Nipple Secretions

Before FNA biopsy found widespread acceptance, the principal cytologic approach to lesions of the breast was the study of **spontaneous secretions of the nipple.**

This method is still valid, but only rarely leads to the **diagnosis of occult intraductal carcinoma.** Efforts have been made to aspirate the breast ducts by means of a specially constructed **breast pump** (Papanicolaou et al, 1958) or by visualization, **cannulation, and aspiration of individual ducts** (Sartorius and Smith, 1977; Sartorius et al, 1977), thus creating artificial nipple secretions. **Ductography**, a procedure that involves injecting the ducts with a radio-opaque substance to determine any abnormalities in the configuration of the lactiferous ducts, is particularly useful in assessing intraductal lesions, whether benign or malignant (Cardenosa and Eklund, 1991). The recent development of an extremely thin two-way catheter has made it possible to perform efficient **lavage of individual breast ducts**

(Dooley et al, 2001; O'Shaughnessy et al, 2002). The cytology of nipple secretions and ductal lavage is discussed in the closing pages of this chapter.

ANATOMY AND HISTOLOGY OF THE NORMAL BREAST

The **female breast** is composed of 15 to 20 **modified sweat glands**. In the resting (nonlactating) adult breast, the glandular portion is composed of **clusters of small secretory lobules or acini (lobular units)**, connected by **small ducts to the main excretory or lactiferous ducts opening into the nipple** (Fig. 29-1). The stroma is composed of loose connective tissue and fat. After menopause, the lactiferous apparatus of the breast undergoes atrophy and the stroma becomes more fibrous.

Each **acinus or lobule** in the resting state is composed of **small cuboidal cells** that line the lumen of the glands, which often contain inspissated secretions. An interrupted layer of **flat myoepithelial cells with clear cytoplasm** surrounds the glandular cells. During **pregnancy**, the **secretory lobules** undergo marked **hypertrophy** and produce first the **colostrum** and, after delivery, **milk**.

The **small ducts** are lined by a layer of **small cuboidal cells**, with an outer interrupted layer of **myoepithelial cells**. The **large lactiferous excretory ducts** are lined by **one to two layers of cuboidal cells that may assume a more columnar configuration as they approach the nipple**. The **myoepithelial cells** form an outer flat layer of cells with clear cytoplasm in the distal part of the secretory ducts. The **lining of the smaller ducts** may undergo apocrine metaplasia, resulting in an epithelium composed of **larger cuboidal cells with eosinophilic cytoplasm** (see below). Soderquist et al (1997) studied proliferation of the mammary epithelium in aspirated samples from 47 healthy young volunteer women. They documented that the proliferation was **dependent on the phase of the menstrual cycle**: it was somewhat higher in the luteal phase, and correlated with serum levels of progesterone.

P.1085

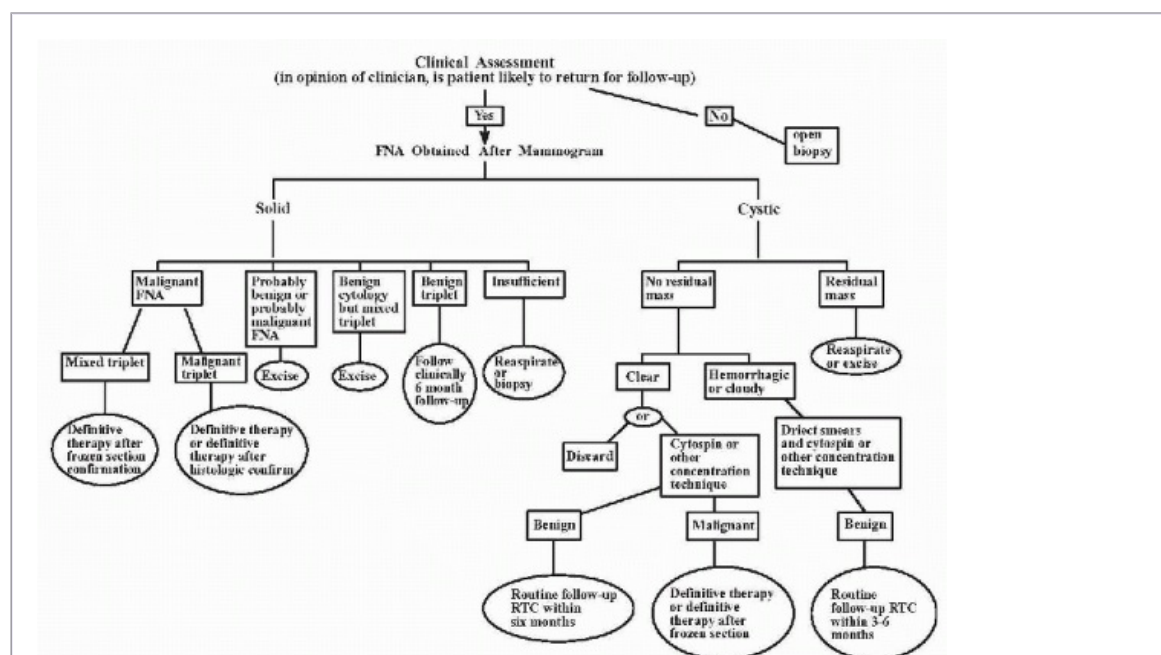

Diagram 29-1 Protocol for patient management proposed by the National Cancer Institute Consensus Conference on the Uniform Approach to Breast Fine-Needle Aspiration Biopsy, 1996, Andrea Abati, M.D., Conference Coordinator. (From Am J Surg 174:371-385,

1997. Courtesy of Dr. Andrea Abati, Bethesda, MD.)

Figure 29-1 Schematic representation of the components of the female breast.

The nipple is composed of rather thick epidermis. **Cells with clear cytoplasm**, which react with antibody to low-molecular-weight keratins (CK 7), are present in normal nipples and may represent an intraepithelial extension of lactiferous duct cells (Toker, 1970; Yao et al, 2002).

Accessory breast tissue may develop along the linea lacta, a breast anlage that stretches from the axilla to the inguinal region. It may be mistaken for a lymph node, particularly in the axilla, and may be recognized by its cytologic presentation (Dey and Karmakar, 1994).

The male breast consists of only sparse ducts surrounded by scarce fat and connective tissue. **The lobular apparatus is absent.**

CYTOLOGY OF NORMAL BREAST

Normal breasts are virtually never aspirated. Thus, the configuration of normal cells is learned from aspirates of benign lesions. The most **common component** observed in aspiration biopsies and other sources of breast cells, such as nipple secretions and ductal lavage, is **cells derived from ducts**. These cells may appear **singly** (usually as **cuboidal**, sometimes columnar cells of various sizes, depending on the caliber

P.1086

of the duct of origin) or as **cohesive clusters composed of cells of equal sizes**. In flat clusters, the duct cells show discernible cell borders (honeycomb clusters) (Fig. 29-2).

The cuboidal cells derived from the lining of **small ductules** are much smaller and are characteristically arranged in **small clusters or sheets**. The **nuclei** of ductal cells are of equal sizes, spherical, and vesicular in configuration, and sometimes containing very small, barely visible nucleoli. **Nuclear folds or creases** may be observed in such cells. **Single ductal cells** have a clear, somewhat eosinophilic cytoplasm that sometimes shows vacuoles, and the same nuclear features as cells in clusters.

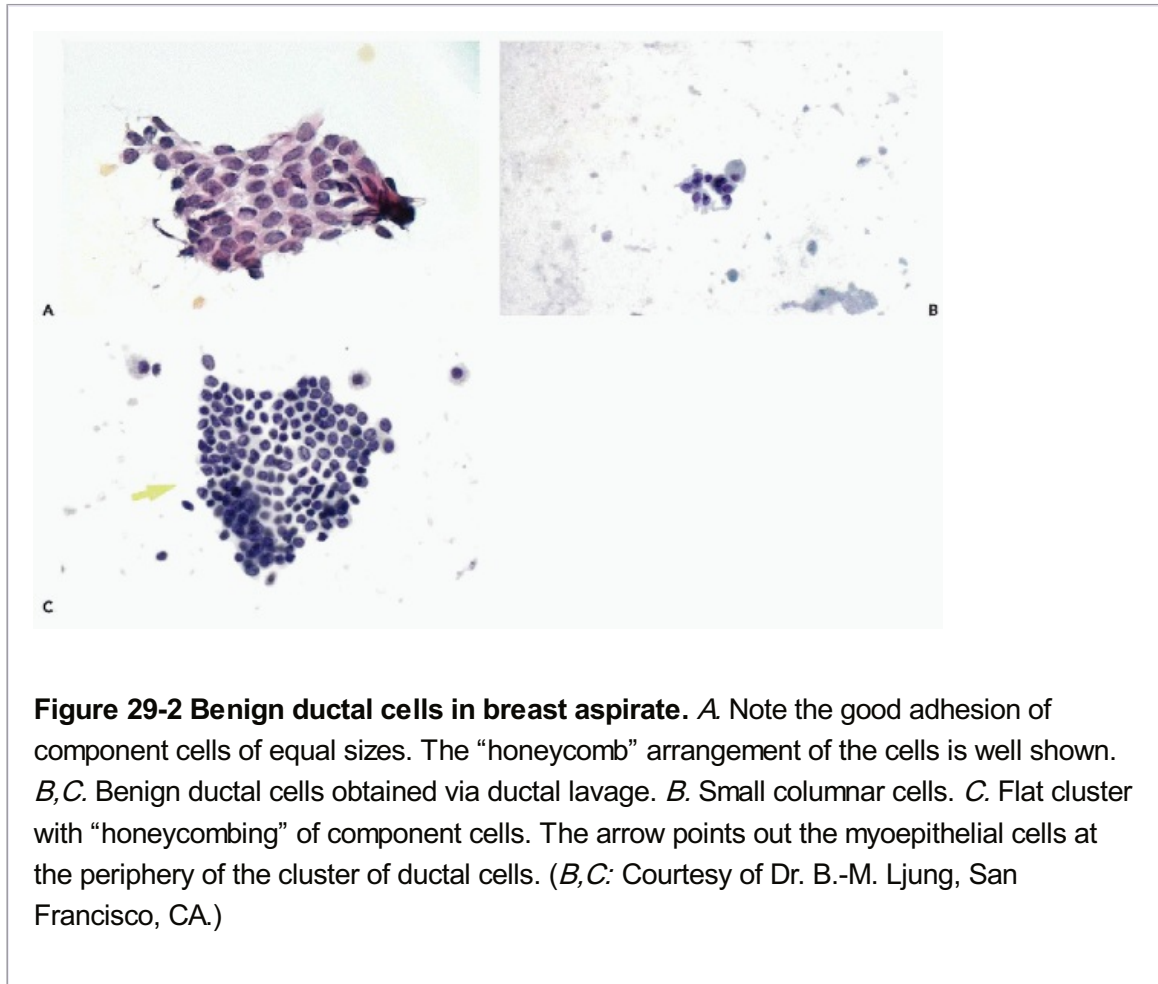

Figure 29-2 Benign ductal cells in breast aspirate. *A.* Note the good adhesion of component cells of equal sizes. The “honeycomb” arrangement of the cells is well shown. *B, C.* Benign ductal cells obtained via ductal lavage. *B.* Small columnar cells. *C.* Flat cluster with “honeycombing” of component cells. The arrow points out the myoepithelial cells at the periphery of the cluster of ductal cells. (*B, C:* Courtesy of Dr. B.-M. Ljung, San Francisco, CA.)

The ductal cells frequently undergo apocrine changes that may be either focal or extensive (Fig. 29-3A,B). The **aspirated apocrine cells**, which occur singly or in small clusters, are larger than normal ductal cells and have abundant, finely granular cytoplasm that is eosinophilic in smears prepared according to Papanicolaou, or slate gray or bluish in smears stained with a hematologic stain. The apocrine cells have spherical, often dense nuclei that vary in size. Occasionally, prominent nucleoli may be seen. Apocrine cells with large nuclei, particularly in the presence of nucleoli, may be misinterpreted as cancer cells (Fig. 29-3C,D). The apocrine cells resemble the **oncocytes** that occur in salivary glands and Hürthle cells in the thyroid (see respective chapters).

Mucus-producing ductal cells, resembling goblet cells, are occasionally found in breast aspirates, especially in fibrocystic disease. They are the dominant cell type in gelatinous or colloid carcinoma (see below). **Secretory ductal cells with clear cytoplasm** also occur in aspirates from breasts with fibrocystic disease.

Normal acinar cells are very rarely seen in aspirates from a normal, nonpregnant female breast, and they should never be seen in a male breast. Occasionally, a cluster of small cuboidal cells is reminiscent of acini. However, **complete lobular units, forming**

approximately spherical, tight, lobulated dense structures, may be observed in **ductal lavage specimens** (Fig. 29-4A). In breast aspirates obtained during **pregnancy and lactation**, the lobular units can be readily recognized (Fig. 29-4B). Also during pregnancy and lactation, the **acinar cells** become much **larger** and show **abundant, vacuolated cytoplasm** and **spherical, often dark nuclei with clearly visible large nucleoli** that may cause diagnostic difficulties, as discussed below (see Fig. 29-21).

Myoepithelial cells are recognizable as **small, spindly, sometimes curved, dark homogeneous bipolar nuclei** with very scanty cytoplasm that may either adhere to epithelial fragments (see Fig. 29-2) or appear singly (Fig. 29-5). In very well processed, air-dried aspiration smears, slender wisps of **elongated cytoplasm** at both ends of the oval nucleus may be observed occasionally (Fig. 29-5D). The presence and recognition of myoepithelial cells is of major diagnostic significance (see below).

The **stroma** of the breast is composed of fat and loose or fibrous connective tissue, which may be observed as tissue fragments. Clusters of **fat cells** are recognizable by their **spherical shape; clear, vacuolated cytoplasm**; and small, compact **peripheral nuclei** (see Fig. 29-10C). The **cells of connective tissue** are slender, short fibroblasts with small, elongated nuclei. These cells often form clusters or bundles, particularly in diffuse fibrosis of the breast (**fibrous mastopathy**, see below) (Fig. 29-6).

P.1087

Figure 29-4 Lobular units. *A.* Ductal lavage of a nonpregnant woman; shows a lobulated structure composed of a cluster of densely packed lobules. *B.* Breast aspirate of a young pregnant woman; shows numerous dispersed lobules. (*A:* MGG stain.) (*A:* Courtesy of Dr. B.-M. Ljung, San Francisco, CA.)

P.1088

Figure 29-5 Myoepithelial cells. The small, slender, sometimes curved "bipolar" nuclei are much smaller in fixed, Pap-stained smears (*A,B*) than in air-dried Diff-Quik-stained smears (*C,D*). *D.* One of the nuclei shows spindly delicate cytoplasm. (*B,D:* High magnification.)

Figure 29-6 Fibrous stroma of breast. *A.* Fibroblasts in loose matrix. *B.* Disorderly cluster of small spindly cells from fibrous mastopathy.

Another common component observed in breast aspirates is the **foam cell**, or large macrophage with vacuolated cytoplasm, which is described in detail in reference to breast cyst content (see Fig. 29-13).

The **lesions of the female breast** listed in Table 29-1 will be discussed in that order.

P.1089

TABLE 29-1 CLASSIFICATION OF LESIONS OF THE FEMALE BREAST

Inflammatory lesions

- Acute and chronic inflammatory processes

Lesions caused by trauma

- Fat necrosis

- Reaction to foreign bodies

- Lesions resulting from breast augmentation or reduction procedures

Benign proliferative disorders

- Cysts

- Fibrous mastopathy and other fibrous lesions of the breast

- Rare benign lesions

Benign tumors

- Fibroadenoma

- Lactating adenoma

- Intraductal papilloma

Granular cell tumor

Rare benign tumors

Malignant tumors

Carcinomas of various types (see Table 29-3)

Sarcomas

Rare tumors and tumorous conditions

Metastatic tumors

INFLAMMATORY LESIONS

Acute and Subacute Mastitis and Abscess

Acute or subacute mastitis and abscess of the breast, which are caused by common pathogenic bacteria, are usually very painful for a patient with a history of recent pregnancy and lactation. A case of mastitis caused by **actinomycosis**, in a middle-aged woman, was reported by Pinto et al (1991). The reasons for aspiration of the breast are the presence of a **palpable mass** or **reddened skin that may mimic an inflammatory carcinoma**.

An aspirate from diffuse suppurative mastitis or a breast abscess usually consists of **semisolid, purulent material** containing numerous **inflammatory cells**, such as granulocytes, lymphocytes, mono- and multinucleated macrophages, and necrotic material. In subacute mastitis, macrophages and lymphocytes prevail. The diagnosis is usually easy. Sometimes, however, large sheets of **atypical epithelial cells** with **somewhat enlarged nuclei and small nucleoli**, and macrophages with enlarged nucleoli present problems for the inexperienced examiner. Nevertheless, careful analysis of the acute inflammatory background in the smear, and the absence of single cancer cells should reveal the benign nature of such aggregates (Fig. 29-7). **It is a sound principle to not render an unequivocal diagnosis of mammary carcinoma in the presence of marked acute inflammation.**

Figure 29-7 Breast abscess. The smear shows numerous polymorphonuclear leukocytes, scattered ductal cells, and necrotic material.

Plasma Cell Mastitis

Plasma cell mastitis is a rare form of breast inflammation that may be associated with **palpable induration and retraction of the skin**, thus mimicking a carcinoma. The active lesions show **periductal inflammatory infiltrates** composed of **lymphocytes and plasma cells**. The ducts are often filled with inspissated secretions.

The nature of the aspirates of these lesions depends on the stage of disease: during the acute stage, clusters of ductal cells and a **mixed population of inflammatory cells** are seen. The **presence of plasma cells is conspicuous**. The lesion may undergo spontaneous healing and fibrosis, and the inflammatory component will be reduced. The cytologic significance of this lesion is **the presence of inflammatory atypia in ductal cells**, which, in view of the disturbing clinical presentation, may be misinterpreted as cancer (Koss et al, 1992).

Subareolar Abscess

Subareolar abscess is a rare disease that affects **women and men** who develop a painful subareolar mass.

A lesion of unknown etiology results from or leads to marked **squamous metaplasia of the lactiferous ducts**, which become obstructed and form a subcutaneous mass. A fistulous tract may result from inadequate treatment (for a recent summary see Lester, 1999). The aspirates of these lesions yield **ductal cells, atypical squamous cells, and anucleated squames**, which are a reflection of squamous metaplasia of breast ducts. Also present are **foreign body giant cells**, which are a reaction to squamous debris (Fig. 29-8). Similar observations have been reported by Galblum and Oertel (1983) and Silverman et al (1986). The lesions must be surgically excised because they will not heal under conservative treatment.

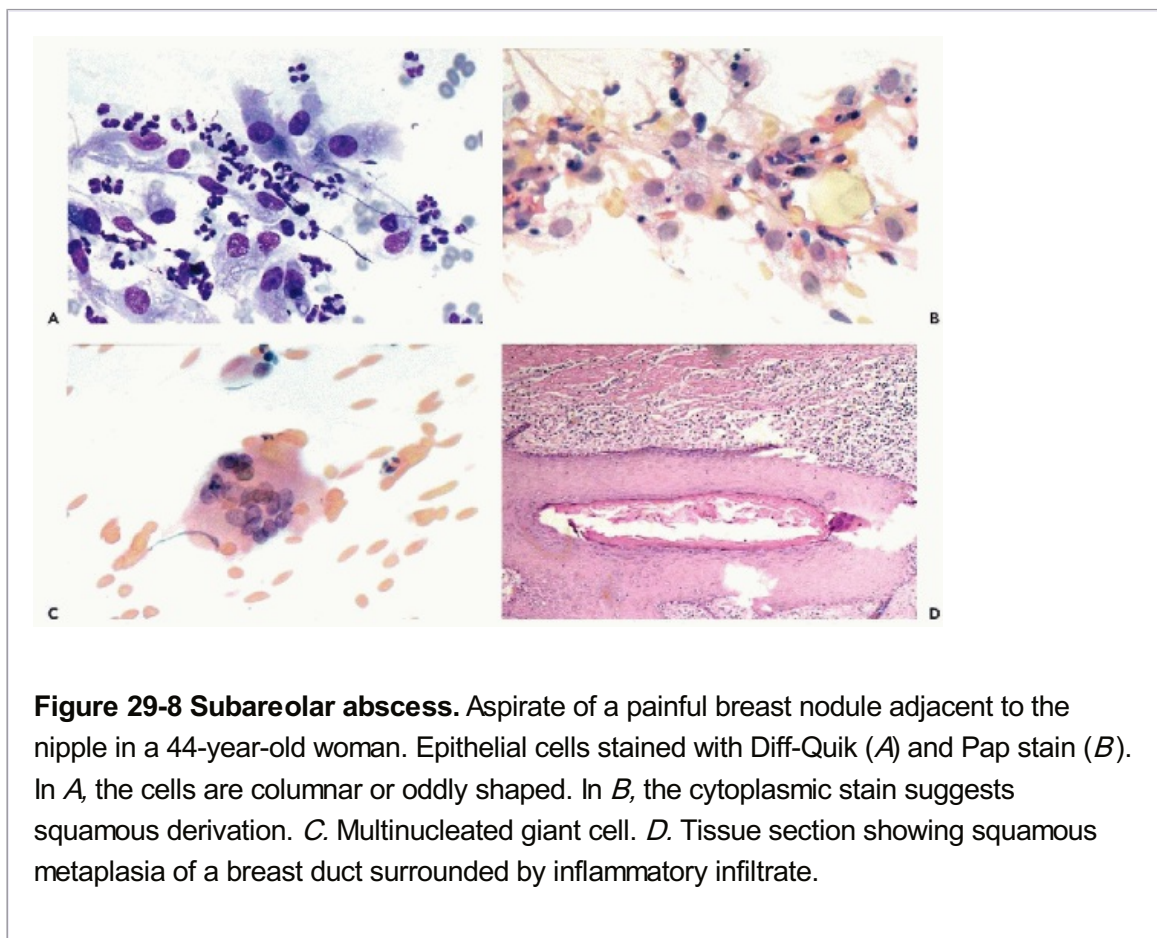

Chronic Inflammatory Conditions

Tuberculosis

Tuberculosis of the breast is much more common in developing countries than in the industrialized world. In a study from India, Shinde et al (1995) examined 100 cases, some

P.1090

of which resulted in ulceration of the breast and required amputation. The histology of the disease is discussed in Chapter 19. Tuberculosis of the breast may **mimic mammary carcinoma with lymph node metastases** because of the presence of a firm breast mass and enlarged, palpable lymph nodes (Woyke et al, 1980). Aspiration of the breast mass reveals a **typical cytologic picture of tuberculosis with granulomas composed of epithelioid cells and multinucleated giant cells of Langhans type**, sometimes accompanied by eosinophilic necrotic material, reflecting **caseous necrosis** (Fig. 29-9). Because of the possibility of confusion with other forms of granulomatous inflammation of the breast, a **confirmation of the diagnosis** by demonstration of acid-fast *Mycobacterium tuberculosis* and by culture is advised.

In a unique case, we also observed a group of **epithelioid cells in the nipple discharge** from a 28-year-old woman known to have tuberculosis of the breast (Fig. 29-9C). Also in India, Nayar and Saxena (1984) observed several cases of tuberculosis of the breast, wherein epithelioid and giant cells of Langhans type were observed in smears of nipple secretions.

Sarcoidosis

Sarcoidosis is discussed at length in Chapter 19. Noncaseating granulomas diagnosed as sarcoidosis were reported by Gansler and Wheeler (1984) in association with a medullary carcinoma of the breast. **Focal granulomatous reaction to malignant tumors** may occur in

various locations, and cannot be considered as a manifestation of sarcoidosis in the absence of systemic manifestations of the disease.

Idiopathic Granulomatous Mastitis

Idiopathic granulomatous mastitis (also known as **granulomatous lobulitis**) is a rare, self-limited disorder of unknown etiology that affects the breasts of young women (Kessler and Wolloch, 1972; Fletcher et al, 1982). **Histologically**, the lesion consists of noncaseating granulomas, micro-abscesses, and inflammatory infiltrate surrounding the lobular areas of the breast. Like tuberculosis, the lesion may **mimic breast cancer**. The **cytology** of these lesions in aspirates is **identical to that of tuberculosis**, except for the absence of acid-fast bacteria and caseous necrosis (Macansh et al, 1990; Kumarasinghe, 1997).

Mastitis Caused by Fungi

Infrequent cases of inflammation of the breast caused by fungi have been observed. Houn and Granger (1991) reported a case caused by **histoplasmosis**, documenting the presence of the fungus in an aspirate. A case of **aspergillosis**

P.1091

was reported by Govindarajan et al (1993). Undoubtedly, other cases of this type will be reported.

Figure 29-9 Mammary tuberculosis. Aspiration smear (*A*) and tissue biopsy (*B*) from the breast of a 43-year-old woman thought to have mammary carcinoma with axillary lymph node metastases. *A*. Granuloma composed of tightly packed elongated epithelioid cells and a giant cell of Langhans' type. *B*. Corresponding tissue section showing multiple granulomas. *C*. Nipple discharge in a 28-year-old woman with tuberculosis of the breast. A cluster of epithelioid cells is shown.

Sclerosing Lymphocytic Lobulitis

Sclerosing lymphocytic lobulitis is an uncommon disorder of the breast that is associated with

diabetes mellitus or **autoimmune diseases, such as Sj rgen's syndrome**. It consists of fibrosis of perilobular tissue associated with a dense lymphocytic infiltrate. The lesions, which have been compared with chronic lymphocytic thyroiditis or Hashimoto's disease, may form palpable masses and thus mimic cancer of the breast. Aspiration biopsies of a few of these lesions have been reported (Abele and Miller, 1994; Miralles et al, 1998). The principal finding was the presence of **numerous benign lymphocytes** and occasional epithelial fragments. The principal point of **differential diagnosis** is **malignant lymphoma** of the breast, as described below.

LESIONS CAUSED BY TRAUMA

Fat Necrosis

Fat necrosis is often observed in women with pendulous breasts that have been subjected to a trauma. Sanchez and Stahl (1996) refer to it as "**grandmothers' disease**" because it is so often observed in grandmothers who sustain a trauma as a result of hugging their grandchildren. However, other forms of trauma, including surgery, may also cause the disorder. The affected area presents clinically as a **firm mass that is partly fixed to the surrounding tissues, thus mimicking carcinoma**.

Aspirates from fat necrosis may contain **amorphous material; fat and inflammatory cells such as neutrophils, lymphocytes, macrophages, and epithelioid cells; and foreign body giant cells in various proportions**. Whereas the **fat cells** in aspirates from the normal breast occur in clusters, in fat necrosis they are **enlarged and dissociated** (Fig. 29-10). Their cytoplasm is often vacuolated, and it may not always be possible to distinguish these cells from large foamy phagocytes. **Ductal cells** may be enlarged but have a normal nucleocytoplasmic ratio. The **macrophages may be quite atypical and show large, multiple nuclei with prominent nucleoli** that may be mistaken for cells of a not further specified malignant tumor (Fig. 29-11). Knowledge of the patient's clinical history, and the characteristic background of the smears with amorphous material and fat cells should be sufficient to prevent errors in diagnosis.

Reaction to Foreign Bodies

Foreign bodies may be introduced into the breast by **prior surgical procedures** (such as suture material). The smears show a typical **foreign body reaction with multinucleated giant cells**, some of which contain fragments of the foreign material, against a background of inflammatory cells. Some necrotic material may be present in the smears.

P.1092

Aspirate of a palpable breast nodule occurring in the scar after breast reduction surgery in a 38-year-old woman. *A.* Large epithelial cells of uneven sizes with eosinophilic cytoplasm and large nuclei and nucleoli. *B.* Biopsy of the breast, showing atypia in the apocrine epithelium of the duct.

Consequences of Breast Augmentation or Reduction

Breast augmentation procedures involving the insertion of silicone implants may result in a reaction to **leakage of silicone** that may cause **palpable lumps** in the breast. If the reaction is also observed in **axillary lymph nodes**, as described by Tabatowski et al (1990) and Santo-Briz et al (1999), it may clinically mimic breast cancer. Cytologic examination of such lesions may be very helpful in the differential diagnosis. The smears show **multinucleated giant cells containing birefringent granular material**.

Breast reduction procedures may also result in palpable **lumps** caused by reaction to suture material, focal fat necrosis, and **fibrosis of mammary parenchyma, which may affect the breast ducts**. In one such case, the FNA aspirate disclosed a foreign-body reaction and **large, markedly atypical duct cells** with enlarged, irregular nuclei and prominent nucleoli. Excision of the breast tissue disclosed focal atypia of ducts, but no evidence of cancer (Fig. 29-12).

BENIGN PROLIFERATIVE DISORDERS

Cysts of the Breast

Pathology and Histology

Single or multiple cysts of various sizes, which are readily identified by sonography, are the **most common cause of a palpable swelling of the breast**. When seen by the surgeon, the cysts may appear bluish in color; hence the term **blue dome cysts** is sometimes used to describe them. For the most part, cysts are a manifestation of fibrocystic disease (see below) and represent a dilatation of obstructed breast ducts. Most cysts are lined by a **single layer of cuboidal or flattened epithelium, which rarely will become multilayered, and occasionally will form papillary projections**. All of the cyst, or parts of it, may be lined by **apocrine epithelium**. The **lumens** of the cysts are filled with fluid, usually inspissated, containing desquamated and large **cells with vacuolated cytoplasm**, known as **foam cells**. Most of the foam cells are undoubtedly macrophages (Krishnamurthy et al, 2002), but some may represent modified duct epithelial cells, as proposed in previous editions of this book and in Papanicolaou's et al (1958) experimental work.

After aspiration, **benign breast cysts should no longer be palpable**. If there is a **residual mass, a reaspiration or tissue biopsy** is suggested to rule out the presence of a mammary carcinoma.

Cytology

Aspiration of breast cysts is a common practice. The aspirated fluid, which ranges in volume from 1 to 10 milliliters, can be clear or opaque, yellow, brown, green, or blood-stained. In general, **clear fluids can be discarded** because they will exceedingly rarely indicate an important lesion. However, **opaque and bloody fluids should be submitted for cytologic investigation**. The fluid must be spun down in a centrifuge, and the sediment must be prepared in the form of **smears**.

Usually the fluid from **benign breast cysts** is fairly rich in vacuolated mononuclear or multinuclear **“foam cells”** of various sizes, and contains various numbers of **benign ductal cells** (occurring singly or in small clusters) that are often poorly preserved. In cysts with **papillary proliferation** of the lining, the epithelial cells are usually more abundant and larger (Fig. 29-13). Cysts for which cytologic analysis of the fluid suggests papillary proliferation **should be excised for histologic study**.

If there is **apocrine metaplasia**, cells with granular cytoplasm, prominent nuclei, and nucleoli may be present. Spherical (“papillary”) clusters of apocrine epithelial cells can be observed (Fig. 29-14). **Some apocrine cells may display very dark, sometimes quite large homogeneous nuclei with prominent nucleoli** (Fig. 29-15). So long as the nuclei are **spherical or oval**, it is likely that they are benign. However, such cells may be mistaken for cells of apocrine carcinoma, wherein the degree of nuclear atypia is usually much greater (see below).

P.1094

P.1095

Figure 29-15 Benign cyst fluid. *A.* Atypical apocrine cells with hyperchromatic nuclei of variable sizes. *B.* Atypical apocrine cells with prominent nucleoli. *C.* Apocrine metaplasia in dilated duct, corresponding to cells shown in *B.*

Several observers have reported the presence of **laminated ring-like structures of various sizes**, known as **Liesegang rings** in cyst fluid (Gupta et al, 1991; Gupta and Naran, 1993;

Gupta, 1996b). Raso et al (1998) analyzed these structures and concluded that they represent precipitable organic substances (see Fig. 25-13). It has been suggested that **Liesegang rings may be the cause of mammographic opacities**.

Primary carcinoma originating in the cyst lining is exceedingly uncommon. The aspiration in such cases contains cancer cells, singly and in clusters. They are in every respect similar to cells of duct carcinoma, as described below.

The differential diagnosis of common cysts includes **a mucocoele-like lesion**, which is a **cystic structure filled with mucus**, as first described by Rosen (1986). These lesions and their **malignant variant** are discussed below along with mucinous (colloid) carcinoma. Another very rare point of differential diagnosis is the **cystic hypersecretory ductal carcinoma**, which may mimic a benign cyst (for a recent summary see Schmitt and Tani, 2000). This lesion is discussed below along with rare malignant tumors of the breast.

Fibrocystic Disease

Histology

Fibrocystic disease of the breast is a common disorder in premenopausal women. It is caused by **sequential proliferation and atrophy of the ducts and lobules**, in synchrony with the menstrual cycle, and subsequent **fibrosis of parenchyma of the breast**. The fibrotic process may cause havoc with the distribution of the ducts, which may then become **obstructed and form cysts** (see above), or show major **disturbances in the pattern of duct distribution**. The fibrotic process also involves the **lobular units**, causing their atrophy.

The epithelium of the **ducts** may also show proliferation or **hyperplasia** in the form of a **multilayer lining that may become focally papillary**, with partial replacement of normal epithelial cells by **oncocytes**. The fibrotic process may also involve the lobular units. A number of entities that are clearly related to each other may result from these events. They have been described as **adenosis, microglandular adenosis, sclerosing adenosis, duct hyperplasia with epithelial proliferation, and dilatation (ectasia) of ducts**. Excessive focal proliferation of the fibrous stroma may result in the so-called **stromal nodules**. All of these changes reflect an imbalance among the acini, ducts, and stroma, and may be observed side by side in the same breast. All may cause a palpable thickening or mass, and abnormalities in mammograms leading to biopsies. Small **deposits of calcified secretions** may be observed in such lesions that may appear on mammograms as **microcalcifications**. Rarely, within some of the small ducts, one may observe **an accumulation of homogeneous eosinophilic spherical structures** surrounded by small ductal cells, a condition known as **collagenous spherulosis** (Johnson and Kini, 1991; Sola-Pérez et al, 1993) (Fig. 29-16). Highland et al (1993) studied the

P.1096

spherical structures by immunochemistry and electron microscopy, and concluded that they may represent a reduplication of the basement membrane.

Figure 29-16 Collagenous spherulosis. *A.* At high magnification, the aspiration smear shows small, homogeneous eosinophilic spherical bodies, measuring approximately 10 μ m in diameter, surrounded by a single layer of small cuboidal cells (high magnification). *B.* Corresponding tissue section showing a small breast duct containing the homogeneous bodies surrounded by small cuboidal duct cells. The lesion must be differentiated from an adenoid cystic carcinoma. (Photographs courtesy of Dr. Sudha R. Kini, Ford Hospital, Detroit, MI.)

Cytology

Regardless of what has been written on the subject of cytology, it is **not possible to differentiate cytologically the various subgroups of benign proliferative breast processes from one another**. A comparison with corresponding tissue sections may be misleading because the smear does not necessarily reflect all of the several types of abnormalities present side by side. Stanley et al (1993), Sidawy et al (1998), and Lee and Wang (1998) reached similar conclusions.

The most commonly aspirated lesions are **small cysts**, which occur in about 40% of women with fibrocystic disease, as shown in 509 consecutive cases with histologic confirmation (Franzén and Zajicek, 1968). Cytology of breast cysts is described above.

Otherwise, the usually **scanty** smears contain **the benign components of breast in various proportions, depending on the type of mastopathy involved**. The **most common component is epithelial cells** that form **flat, cohesive clusters** and are accompanied by **spindle-shaped, “bipolar” myoepithelial cells** (see Figs. 29-2 and 29-5). **Apocrine cells or oncocytes**, some of which show large hyperchromatic nuclei, **occur singly or in small, cohesive flat sheets** (see Fig. 29-3). **Various numbers of foam cells** may be present (see Fig. 29-13). Sometimes **fragments of stroma**, composed of loosely structured bundles of spindly, elongated fibroblasts with benign nuclei, may be observed (see Fig. 29-6). **Necrotic material** may be present in cases with marked dilatation of ducts, containing inspissated secretions (**duct stasis and inflammation**). In the previous edition of this book, Zajicek pointed out that in **air-dried smears** prepared with hematologic stains, dark-staining nuclei and a **“dirty” appearance of the cytoplasm** are additional signs by which epithelial cell clusters aspirated from benign intraductal proliferation can be identified. In this respect, the air-dried smears are superior to wet-fixed smears. In a study of patients with fibrocystic disease, Linsk et al (1972) observed larger sheets of epithelial cells in 4% of the patients, and stromal fragment in only 2%. Both findings have also been observed in fibroadenomas (see below).

The proliferation of duct epithelium with formation of intraductal papillary structures can be very marked in very young women with cystic disease of the breast (**juvenile papillomatosis**). In such young patients, whose breasts are very rarely aspirated, the epithelium may be abundant and the smear pattern may mimic a fibroadenoma (Ostrzega, 1993).

In the rare **collagenous spherulosis**, the spherical structures (measuring 10 to 20 μm) are metachromatic and surrounded by small epithelial cells (Fig. 29-16). These findings may **mimic adenoid cystic carcinoma**, which is a very uncommon malignant lesion in the breast, as discussed below (Johnson and Kini, 1991; Tyler and Coghill, 1991; Highland et al, 1993; Solá-Pérez et al, 1993).

We have never seen **myspherulosis or small cystic structures (measuring 5 to 7 μm in diameter)** that contain skeletons of red blood cells. Such cells are usually a consequence of a surgical procedure and were observed in breast aspirates by Shabb et al (1991).

In about 95% of the aspirates of benign proliferative lesions of the breast, it is relatively simple to recognize that the process is benign, based on the arrangement of epithelial cells in orderly flat sheets and the presence of “bipolar” myoepithelial cells. In a relatively small number of these cases, **diagnostic problems** may be encountered. Such dilemmas occur when the **epithelial cells in smears show enlarged nuclei and visible nucleoli** (see Fig. 29-20). Depending on the proportion of such cells, the smears are considered as “**atypical**” and **sometimes as suspicious**. Another source of possible error is the presence of **complex tubular structures** (Fig. 29-17) that may occur in smears derived from atypical ductal hyperplasia, the rare **micro-glandular**

P.1097

adenosis, or tubular adenoma, and may **mimic tubular carcinoma** as described below (Silverman et al, 1989; Shet and Rege, 1998). Under these circumstances, an outright diagnosis of cancer should not be made, because the **abnormal cells or clusters usually appear in the company of clearly benign cells and myoepithelial cells**, whereas in smears of most carcinomas, the population of malignant cells is “pure.” Further, in most benign cases, the **proportion of detached, single abnormal cells is very small**, whereas they are common in cancer (see below).

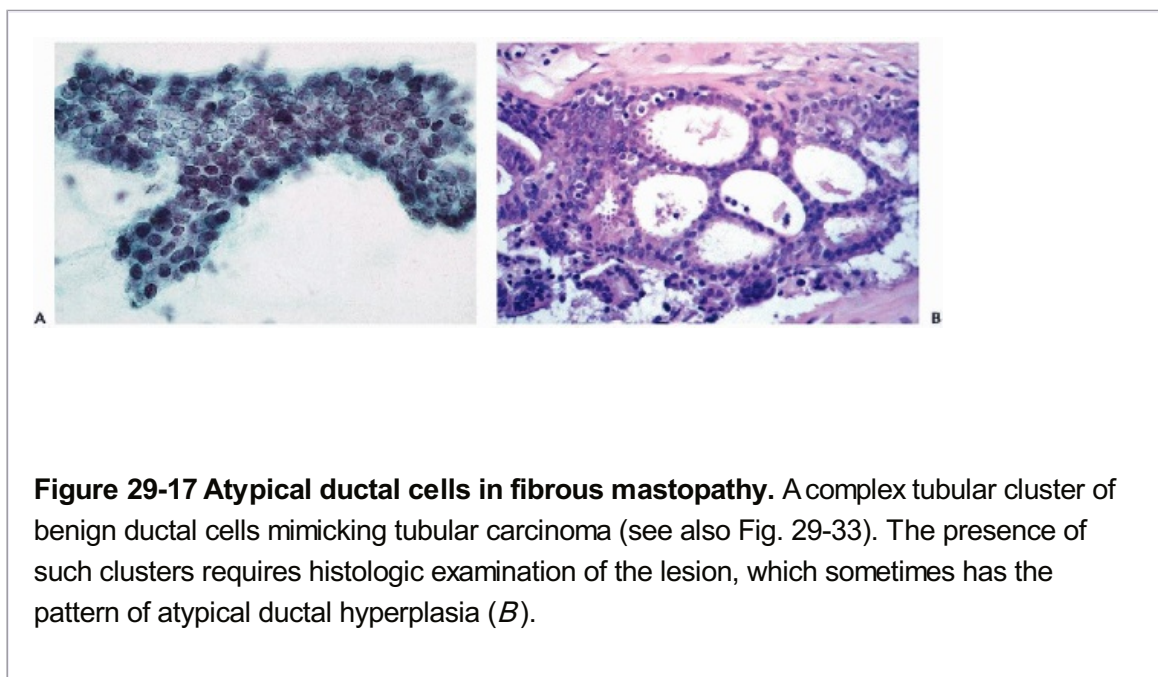

Figure 29-17 Atypical ductal cells in fibrous mastopathy. A complex tubular cluster of benign ductal cells mimicking tubular carcinoma (see also Fig. 29-33). The presence of such clusters requires histologic examination of the lesion, which sometimes has the pattern of atypical ductal hyperplasia (B).

Over the years, numerous papers have analyzed the patterns of smears in proliferative disease of the breast, leading to one inescapable conclusion: in a very small number of these cases, **diagnostic errors will be made**. For further discussion of errors in cytologic diagnosis, see below.

Fibrous Lesions

Fibrosis of the stroma of the breast may assume various forms (McMenamin et al, 2000). When the fibrosis is very extensive and composed of firm, collagenous tissue, the aspirates may be difficult to perform and will be **very scanty** (Bardales and Stanley, 1995). Because similar conditions may prevail in scirrous carcinoma of the breast (see below) they may be a cause for concern. Still, the cells in aspirates of fibromatosis such as **small spindly fibroblasts** or occasional **fragments of epithelium** (see Fig. 29-6) are usually clearly benign (el-Naggar et al, 1987; Zaharopoulos and Wang, 1992; Lopez-Ferrer et al, 1997). Two cases of extremely rare breast fibromatosis with **spherical intracytoplasmic inclusion bodies** of unknown derivation or significance were described by Pettinato et al (1994).

A source of diagnostic confusion may be **nodular (pseudosarcomatous) fasciitis**, a benign, self-limiting **subcutaneous lesion that is usually caused by trauma** and is uncommon in the breast. In such lesions, a rich population of atypical spindly cells (some with large nuclei and prominent nucleoli) may occur, and may be confused with a spindle cell sarcoma (Dahl and Åkerman, 1981). An example of this type of lesion is shown in Figure 6-10. **The complete involution of such a lesion after aspiration biopsy** was described by Stanley et al (1993b). Another possible source of diagnostic difficulty is the **very rare low-grade fibromatosis-like carcinoma** (Sneige et al, 2001), which is likely to shed spindly cells in aspirated material. The spindle cell lesions of the breast are exceptional. If the diagnosis of FNA is not crystal clear, it is wise to withhold a final opinion and request a tissue biopsy.

BENIGN NEOPLASMS

Fibroadenoma

Histology

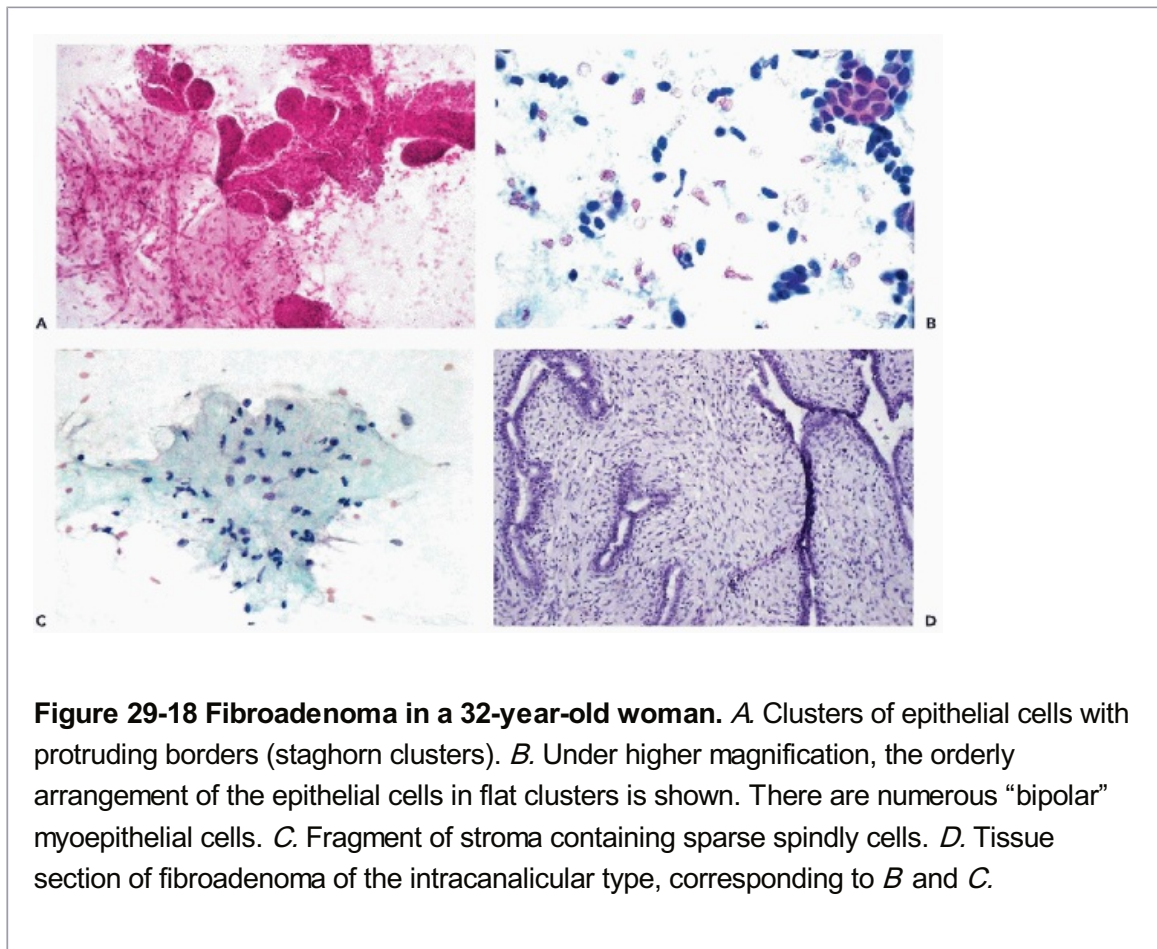

Fibroadenomas are encapsulated benign breast tumors that occur predominantly in young women. They are characterized by the proliferation of **connective tissue stroma and the ductal epithelium**.

Clinical examination characteristically reveals a **firm, freely mobile, well circumscribed mass** that in younger patients may be confused with a **cyst or a lipoma**, and in the elderly may be confused with a **carcinoma**. Two histologic variants of fibroadenoma are generally recognized: **pericanalicular fibroadenomas** consist of ducts surrounded concentrically by connective tissue, whereas the **intracanalicular type** results from invagination and distortion of ducts by proliferation of subepithelial connective tissue (Figs. 29-18D and 29-19D). This classification has **no prognostic value**. The amounts of the fibrous and epithelial components vary from case to case. **Hyalinization and calcification** of the lesions are common, especially in elderly patients. **Large fibroadenomas** with marked **proliferation of stroma** are often classified as **cystosarcoma phyllodes, or phyllodes tumors** (see below). Rarely, **primary ductal or**

P.1098

lobular carcinomas (in situ or invasive) may occur within fibroadenomas, as shown in

Figure 29-39.

Cytology

The aspirates of fibroadenomas are characterized by **numerous large sheets of benign mammary epithelium, sometimes arranged in angulated (staghorn) clusters and, in most cases, fragments of loose connective tissue stroma, either homogeneous or composed of small spindly cells. The bipolar myoepithelial cells are abundant** (Fig. 29-18). In air-dried smears processed with a hematologic stain, the **sheets of epithelial cells** are larger, **more complex**, and **multilayered**, and the cells tend to surround empty circular spaces, **suggestive of gland formation**. The **stroma** of the lesion appears as a homogeneous, **magenta-staining** structure. Other components of these smears are discussed above (Fig. 29-19). In the rarest cases, the presence of **multinucleated giant cells** may be observed (Fig. 29-20D). These findings, in combination with a well-circumscribed mass, are **strongly suggestive of a fibroadenoma**. However, in some fibroadenomas, the smears contain only a scanty population of epithelial cells and very few, if any, stromal fragments. Such smears are similar to those observed in diffuse proliferative fibrocystic breast disorders, as discussed above (Linsk et al, 1972). The **differential diagnosis** usually rests on clinical and mammographic findings of a localized nodule vs. diffuse thickening of the breast.

Occasionally, **clusters** or scattered **epithelial cells with markedly enlarged nuclei containing visible and enlarged nucleoli** may occur in a fibroadenoma (Fig. 29-20). These fortunately very rare cases pose a diagnostic dilemma between a **fibroadenoma with atypia** and a **mammary carcinoma, possibly occurring within the fibroadenoma**. In such cases, a **histologic study of the lesion is mandatory**.

Galactocele and Lactating Adenoma

Palpable, nodular lesions in the breasts of pregnant or lactating women require prompt attention because they may represent a **galactocele**, a **benign adenoma**, or a **carcinoma**.

Galactoceles are cysts filled with droplets of colostrum or milk, and clusters of **large epithelial cells with dropletfilled cytoplasm** that mimic foam cells (Novotny et al, 1991). Raso et al (1997) described a case of **crystallizing galactocele** with milky fluid and the presence of crystals.

Aspiration biopsy of the breast in **lactating adenoma** yields features typical of the **lactating breast: numerous, densely packed lobular units**, either in clusters or as **isolated**

P.1099

spherical structures, with myoepithelial cells at the periphery. Some of the clusters break up in the process of smear preparation and form **flat sheets of cells with cytoplasm studded with large vacuoles, representing colostrum, and spherical nuclei of equal sizes, each containing one or more prominent, large, sometimes irregular nucleoli** (Fig. 29-21). In some cases the fragile cytoplasm of the cells disintegrates, and **only nuclei stripped of cytoplasm (naked nuclei)** are observed. The cytoplasmic debris forms a hazy background on the smear. It is the presence of the large nucleoli that may mislead an uninformed observer into believing that cancer is present. This error must be avoided at all costs, as it may have tragic consequences. Zajicek (1974, 1977) pointed out that certain **superficial similarities** in cell distribution in smears, and the presence of large nucleoli exist between cells derived from acini of a lactating breast and cells of medullary carcinoma. This similarity is spurious because the **degree of cellular and nuclear abnormality in medullary carcinoma (described below) is significantly greater** than that observed in cells derived from a lactating breast. Still, this example does call attention to the **dangers of cytologic diagnosis of mammary carcinoma during pregnancy and lactation**, particularly because **duct cancers may also occur in such women** (Novotny et al, 1991).

Figure 29-19 Fibroadenoma in a 39-year-old woman, with Diff-Quik stain. *A.* Numerous clusters of epithelial cells and myoepithelial cells in the background. *B.* Under higher magnification, the complexity of the multilayered cluster is evident. The circular

empty spaces are not an artifact; they mimic gland formation and correspond to the ducts in the tumor. *C.* Fragments of stroma, staining magenta, surrounded by numerous epithelial cell nuclei. *D.* Tissue section of fibroadenoma of the pericanalicular type, corresponding to *A-C*.

Nipple Papillomatosis (Florid Papilloma of the Nipple)

Nipple papillomatosis characteristically involves the terminal lactiferous ducts. This benign entity forms an **intricate network of proliferating ducts and tubules** that may be mistaken for a carcinoma in a histologic section. The lesion often causes a visible **deformity of the nipple**.

Usually the cytology of such lesions is easily classified as benign, inasmuch as the **cuboidal or columnar epithelial cells form cohesive sheets**, akin to those seen in fibroadenomas, which are usually **accompanied by myoepithelial cells** (Koss et al, 1992). Similar observations have also been reported by Mazzara et al (1989) and Pinto and Mandreker (1996).

Granular Cell Tumor (Myoblastoma)

The granular cell tumor (myoblastoma) is an uncommon, firm, benign tumor of the breast. It may reach a substantial

P.1100

size (2 to 3 cm) and **clinically mimic a carcinoma**. It is important to recognize in the aspiration smear (and in the histologic section, for that matter) the **characteristic large cells with abundant granular cytoplasm and fairly monotonous, generally spherical small nuclei** without distinguishing features (Fig. 29-22). In smears, a break-up of the cytoplasm is a common feature that results in "naked" nuclei. The lesion should not be confused with a large-cell duct carcinoma or the exceedingly rare myoblastomatoid carcinoma (Cohen et al, 1997). An exceptional case of coexisting granular cell myoblastoma and infiltrating duct carcinoma was reported by Al-Ahmadi et al (2002).

Figure 29-20 Fibroadenoma with atypia. *A.* A 39-year-old patient. *B.* A 38-year-old patient. Two examples of clusters of atypical epithelial cells with prominent nucleoli. *C.* Fibroadenoma in a 28-year-old patient who was 6 months pregnant. Note the slight nuclear enlargement. *D.* Multinucleated giant cell in a smear of a fibroadenoma—a rare but benign finding.

Miscellaneous Benign Tumors

The breast may be the site of a variety of **benign soft-tissue tumors** that may also occur in other organs. Some of these tumors may be recognized in aspiration smears, and others may be described after the lesion is identified in histologic sections. These tumors are discussed at length in Chapter 35.

Myofibroblastoma

The myofibroblastoma is an uncommon benign lesion of the breast. It was first recognized by Wargotz et al (1987) as a distinctive nodular tumor composed of interlacing bundles of fibroblasts and smooth muscle cells, thus mimicking other fibrous tumors. This tumor is **more common in male than in female breasts**. Nguyen et al (1987), Ordi et al (1992), Dei Tos et al (1995), and Lopez-Rios (2001) described aspiration biopsy findings in male patients. The presence of **naked nuclei with grooves** accompanying **loosely structured clusters of benign spindly cells** is found in smears of this rare lesion. It is doubtful that an accurate diagnosis of this tumor can be established from aspirates.

Adenomyoepithelioma

Adenomyoepitheliomas are extremely uncommon tumors composed of bundles of spindly cells, presumed to be myoepithelial cells, with an admixture of epithelial tubules and glands (Rosen, 1987). A malignant variant of this tumor has been described (Loose et al, 1992). Birdsong et al (1993), Nilsson et al (1994), Valente et al (1994), and Laforga (1998) each described the cytology and histology of one such case. Kurashina (2002) described two cases (one benign and one malignant). Birdsong et al (1993) observed clusters of **metachromatic stromal cells in association with epithelial cells. The smears were similar to findings in phyllodes tumors (see below)**. Kurashina (2002) described

P.1101

bundles of spindly cells with an admixture of epithelial cells. In the malignant case, the nuclei of the spindly cells showed enlarged, hyperchromatic nuclei with visible nucleoli. The tumor obviously mimics all other fibrous changes in the breast. Although we have had no personal experience with this tumor, we doubt that it can be accurately recognized in a cytologic sample.

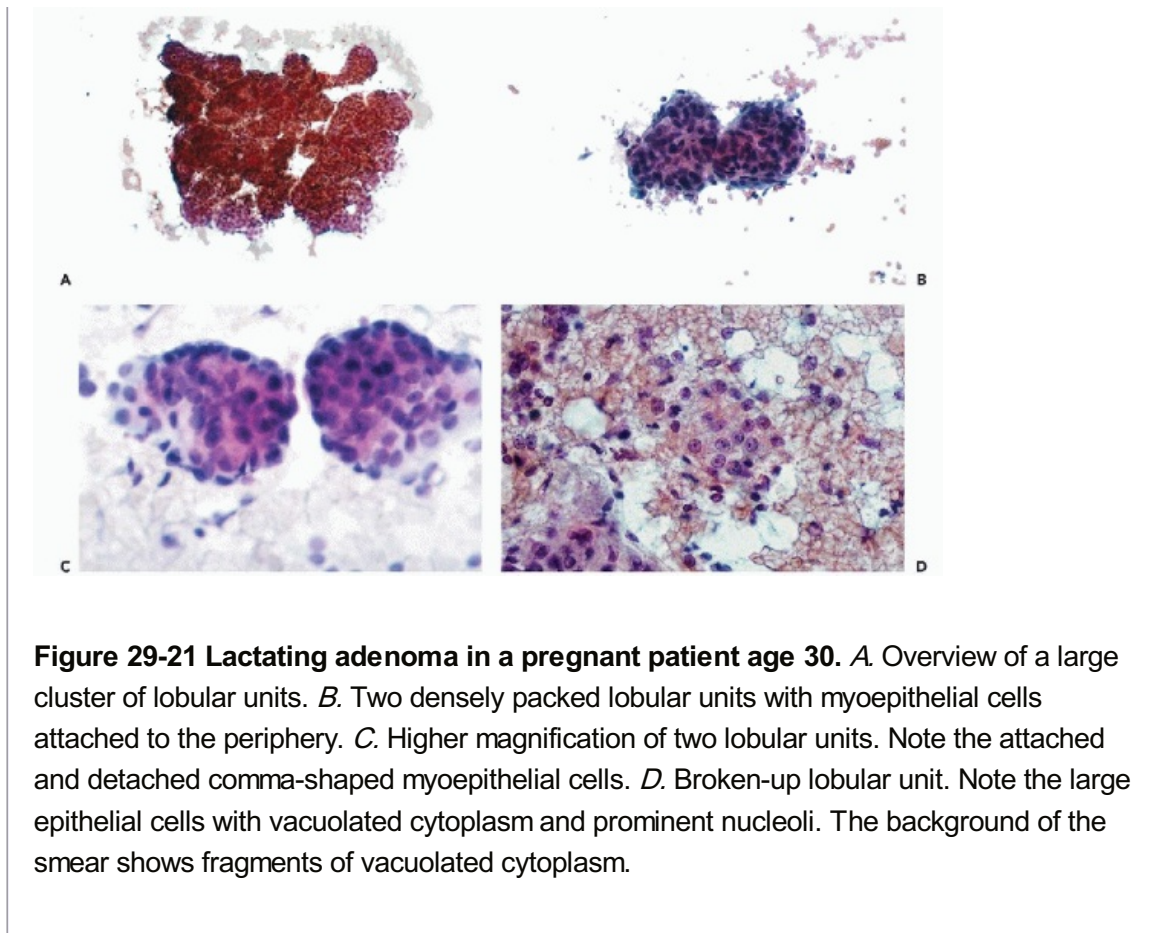

Figure 29-21 Lactating adenoma in a pregnant patient age 30. *A.* Overview of a large cluster of lobular units. *B.* Two densely packed lobular units with myoepithelial cells attached to the periphery. *C.* Higher magnification of two lobular units. Note the attached and detached comma-shaped myoepithelial cells. *D.* Broken-up lobular unit. Note the large epithelial cells with vacuolated cytoplasm and prominent nucleoli. The background of the smear shows fragments of vacuolated cytoplasm.

Pleomorphic Adenomas

Pleomorphic adenomas, which are common in **salivary glands**, may occasionally occur in the breast and may clinically mimic a carcinoma (Kanter and Sedeghi, 1993). Their histologic and cytologic presentation is identical to that of the salivary gland tumors, described in Chapter 32.

Other Benign Tumors

Hemangiomas cannot be recognized in aspiration biopsies. The smears contain blood, sometimes with a few spindly stromal cells.

Lipomas yield only clusters of fat cells, either of normal configuration or somewhat enlarged. If significant **nuclear abnormalities** are present, the possibility of a **liposarcoma** must be considered.

Neurilemmomas (schwannomas) may occur in the breast. For a discussion and illustration of these tumors, see Dahl et al (1984) and Chapter 37. Fisher et al (1990) described a neurilemoma in an aspirate of the breast.

Skin Tumors

Virtually all diseases and tumors of the skin may affect the breast (Koss and Robbins, 1976).

Benign tumors of the skin sweat glands, such as eccrine spiradenoma (Bosch and Boon, 1992) **and hidradenoma** (Kumar and Verma, 1994) have been observed in breast aspirates (see Chap. 34).

Table 29-2 summarizes the principal cytologic observations in most common benign lesions of the breast.

TUMORS THAT MAY NOT BE RECOGNIZED AS EITHER BENIGN OR MALIGNANT

Phyllodes Tumor (Cystosarcoma Phyllodes)

Histology and Clinical Data

Phyllodes tumors represent less than 1% of palpable tumors of the breast. The ancient **name** of these tumors is based on the gross appearance of tumor nodules shaped like leaves (from Greek, *phyllon* = leaf). Although the term *sarcoma* was originally attached to them, these tumors represent **large fibroadenomas** of uncertain behavior, hence the currently preferred term *phyllodes tumor*. Clinically, the tumor presents as a **large, fairly well-demarcated mass**, sometimes with a history of rapid enlargement. Histologically, the tumors resemble a fibroadenoma with the salient feature of an **increase of the periductal stroma**. The stroma may be composed of benign fibroblasts, identical to those of a fibroadenoma (**benign phyllodes tumor**), or large and sometimes bizarre malignant cells with frequent mitoses (**malignant phyllodes tumor**). Some observers add an intermediate category, the **borderline phyllodes tumor**, which has increased cellularity and only slight atypia of the stroma (Bhattari et al, 2000). **Apocrine metaplasia**, **keratin cysts**, and **bony metaplasia** have been observed in these tumors (Stanley et al, 1989; Insabato et al, 1990; Agarwal et al, 1991). Regardless of their designation as benign, borderline, or malignant, all phyllodes tumors receive **the same treatment**: unless the tumor shows evidence of local invasion or metastatic spread at the time of surgery, it is treated by wide local excision.

Figure 29-22 Granular cell myoblastoma. A,C. Tumor in a 32-year-old woman. A. Air-dried MGG-stained smear showing a population of large cells with pale granular cytoplasm and spherical nuclei. Cytoplasmic fragments are seen in the background. B. Alcohol-fixed, Pap-stained smear from a 30-year-old woman. The granularity of the cytoplasm is better shown. C. Tissue section corresponding to A, showing sheets of tumor cells with granular, eosinophilic cytoplasm. (Case courtesy of Dr. Miguel Sanchez, Englewood Hospital, Englewood, NJ.)

TABLE 29-2 PRINCIPAL CYTOLOGIC FEATURES OF COMMON BENIGN LESIONS OF THE FEMALE BREAST IN FNA

	Duct cells	Apocrine cells	Myoepithelial cells	Foam cells	Other findings
Breast cysts	Sparse	Often numerous	Absent	Numerous	
Fibrous mastopathy	Variable size clusters	Variable	Present	Rare	Stromal fragments often present
Abscess	Poorly preserved	Absent	Absent	Absent	Acute inflammation and necrosis
Fat necrosis	Sparse	Absent	Absent	May be present	Atypical fat cells and macrophages
Tuberculosis & sarcoidosis	Sparse	Absent	Absent	Absent	Tubercles with giant cells; necrosis in Tbc, not in sarcoid
Fibroadenoma	Abundant in large angulates, clusters	Rare	Numerous	Absent	Stromal fragments common; atypia of ductal cells fairly frequent
Granular cell myoblastoma	Absent	Absent	Absent	Absent	Large cells with granular cytoplasm

Aspiration smears are characteristically **highly cellular** and are dominated by sheets of epithelial cells (identical or similar to those seen in fibroadenomas) and fragments of **spindly or polygonal stromal cells, some showing nuclear atypia**. The degree of nuclear atypia present in stromal cells varies from case to case. In some tumors, the **nuclei are monomorphic and identical to or only slightly larger than the nuclei in ordinary fibroadenoma**. In other cases, the **nuclei vary considerably in size and shape and may show hyperchromasia, with fairly numerous mitoses, suggesting a malignant neoplasm**. In rare cases, bizarre cancer cells may be observed, corresponding to cystosarcomas with fully malignant stroma (Fig. 29-23). Agarwal et al (1991) reported the presence of **keratin debris** in a case with keratin inclusion cyst. Stanley et al (1989) reported the presence of **apocrine cells**. Lee et al (1998) reported a case of a malignant phyllodes tumor with **liposarcomatous stroma**, confusing the cytologic picture still further.

Smears from a phyllodes tumor pose two diagnostic dilemmas:

- Is the lesion an ordinary fibroadenoma or can it qualify as a phyllodes tumor?
- In cases with marked abnormalities of stromal cells, is it a phyllodes tumor or a carcinoma?

Although it may not be possible to distinguish between fibroadenoma and phyllodes tumor by FNA, a cellular stroma with plump spindle cell nuclei suggests the latter.

Figure 29-23 Phyllodes tumor with malignant stroma. *A*. Bizarre malignant cells derived from the stroma of a phyllodes tumor, shown in *B*. (*A*: Giemsa stain, high magnification. *B*: H&E.)

Deen et al (1999) were unable to differentiate benign or borderline phyllodes tumor from fibroadenomas, but recognized two malignant phyllodes tumors because of **bizarre nuclei in tumor cells** and the **absence of myoepithelial cells**. In principle, the cytologic picture of stromal cells is fairly characteristic and should readily permit differentiation from carcinoma, except in the very rare cases of metaplastic spindle cell carcinoma (Sneige et al, 2001). Nevertheless, the differential diagnosis between phyllodes tumor and carcinoma may cause **significant difficulties**. Thus, two experienced observers, Dusenbery and Fable (1992), pointed out that in aspirates with scanty stroma, the lesions may be confused with a carcinoma. **Clearly, the cytologic diagnosis of phyllodes tumor is fraught with many pitfalls that can only be resolved by excision of the tumor and histologic assessment.**

Papillary Tumors (Duct Papilloma and Papillary Carcinoma)

Histology and Clinical Data

Another group of breast tumors that may cause significant diagnostic problems is the **papillary tumors**. The main secretory ducts are the most common sites of these neoplasms, which are often associated with nipple discharge that is sometimes hemorrhagic, as described and illustrated below. **Benign duct papillomas may be single or multiple, and can be visualized by ductography** (Cardenosa and Eklund, 1991). Under development is **fiberoptic ductoscopy**, which allows a direct visualization of the lesion (see the end of this chapter). Histologically, the lesion is composed of a branching connective tissue stalk surrounded by folds of benign epithelium of the ductal type. **Papillomas and papillary carcinoma**, which may occur in the lining of breast cysts or in ducts, are similarly constructed and show **various levels of epithelial cell abnormalities**. A **firm diagnosis** of invasive papillary carcinoma can be rendered only on the basis of histologic material showing **invasion of parenchyma of the breast** beyond the confines of the duct of

P.1104

origin, or the presence of carcinoma in the adjacent ducts. As is the case with phyllodes tumor, benign and malignant intraductal papillary tumors receive the same treatment, which consists of a **wide excision of the lesion**, followed by radiotherapy. The palpable lesions can be aspirated.

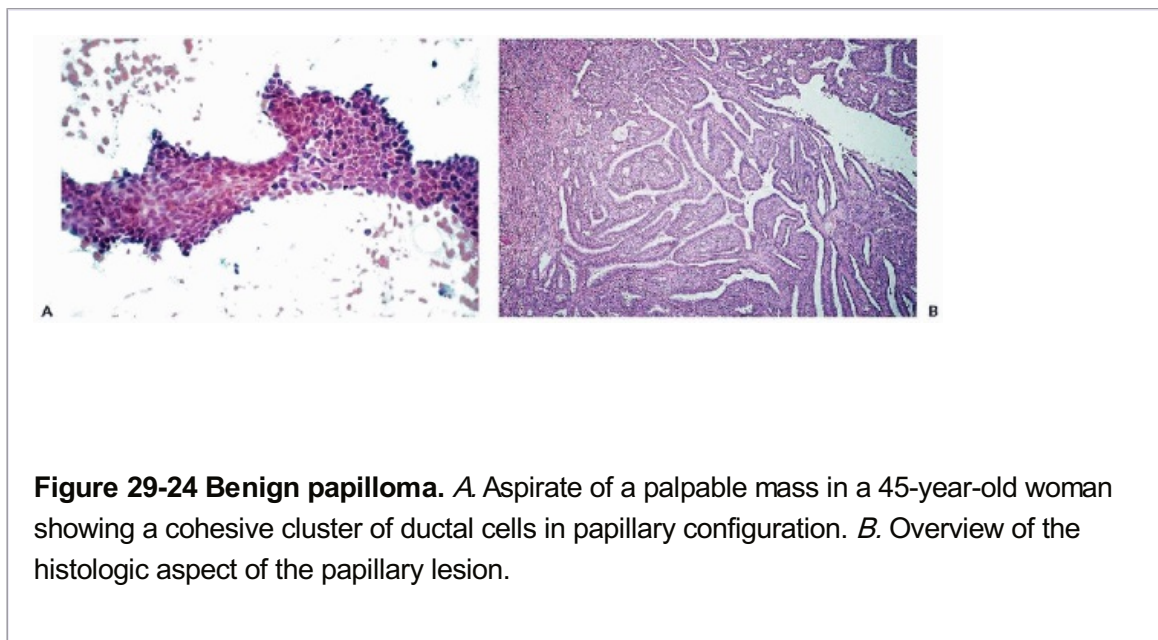

Figure 29-24 Benign papilloma. *A.* Aspirate of a palpable mass in a 45-year-old woman showing a cohesive cluster of ductal cells in papillary configuration. *B.* Overview of the histologic aspect of the papillary lesion.

Cytology

Aspiration of **benign papillary duct lesions** usually yields a droplet of clear fluid or blood, and contains epithelial fragments. The smears usually show **cuboidal or columnar ductal epithelial cells**, which mainly form large cohesive clusters (Fig. 29-24). In single cells, the cytoplasm may show vacuoles that may range from small to very large, occupying a large portion of the cytoplasm. Transitional forms between normal epithelial cells and vacuolated cells can be observed. Clusters of **apocrine cells**, some showing chromatin clumping and pyknotic nuclei, and sometimes **myoepithelial cells**, may also be observed.

In the experience of this laboratory, **malignant papillary tumors are rare**. Aspiration smears contain **cell clusters** that may be very similar to those observed in benign papillomas (see Fig. 29-34). Isolated malignant cells are infrequent. **There is an occasional nuclear enlargement**

in epithelial cells, and sometimes evidence of mitotic activity (Koss et al, 1992; Bardales et al, 1994). Dawson and Mulford (1994) noted that **increased cellularity and the absence of apocrine cells** in smears favors a malignant lesion. These authors also pointed out that **infarcted papillomas** may shed highly abnormal cells, and are the source of significant diagnostic difficulty. In a previous publication, we suggested that a **reliable cytologic diagnosis of a papillary carcinoma cannot be made**, and that all papillary lesions observed in cytologic material should be excised for histologic examination (Koss et al, 1992). We have no reason to change this opinion. There are rare exceptions to this rule, such as when the smear shows clear-cut evidence of carcinoma and the malignant lesion has a papillary configuration (see Fig. 29-34). Masood et al (2003) concluded that core needle biopsies are not superior to aspiration cytology in solving this dilemma. The very uncommon **solid papillary carcinoma** of the breast is discussed below with intraductal carcinomas.

CARCINOMAS

Classification

For the purpose of cytologic diagnosis, a simple classification of mammary carcinomas is provided in Table 29-3. **The histology of these tumors is discussed below for each tumor type. Not all of these types and subtypes of mammary cancer can be securely identified in aspirates. Some are easy to diagnose and others may present substantial difficulties.**

General Cytologic Presentation

Aspirates obtained directly from most (but not all) mammary carcinomas yield **an abundant pure population of cancer cells, singly and in clusters**. In most cases, **the smear background is clear, with no evidence of inflammation or necrosis**. Depending on the tumor type, cancer cells can **vary enormously in size**, from very large to very small (barely larger than lymphocytes). Usually, cells of **approximately the same type predominate in each individual tumor**.

In some cancers, **cluster formation is dominant**, whereas in others the **cells are mainly dispersed** (Fig. 29-25). These patterns may be of prognostic significance (see below). Not all breast cancers shed abundant cancer cells: the fibrosing (**scirrhous**) duct cancer may yield only a **scanty population of cancer cells**. The special presentations of some types of mammary carcinoma are discussed below.

Clusters of aspirated cancer cells in breast cancer are often **three-dimensional** (i.e., composed of several superimposed layers of cells). These clusters are **loosely arranged**, and consequently the **cells at the periphery of the cluster tend to become detached**. This cell arrangement differs

P.1105

from cell clusters in benign lesions of the breast, which are generally tight and often flat (compare Figs. 29-17 and 29-18 with Fig. 29-25). The presence of **single, detached cancer cells** is of great diagnostic value, and **in their absence a diagnosis of breast cancer should be made with extreme caution**. Isolated **cancer cells** vary in configuration and usually display the customary evidence of cancer, i.e., **changed nucleocytoplasmic ratio and nuclear abnormalities such as irregular nuclear contour, hyperchromasia, and, mainly, large and multiple nucleoli**. The tumors may be classified as to their **nuclear grade**, with grade I showing monotonous smaller nuclei, grade III showing large nuclei with prominent large

nucleoli, and grade II being intermediate between the two extremes. The prognostic significance of nuclear grading is discussed below. **The absence of myoepithelial cells** is an important diagnostic clue. If **such cells are present in the smear, extreme caution** is advised before one makes a diagnosis of cancer.

TABLE 29-3 CLASSIFICATION OF MAMMARY CARCINOMAS

Carcinomas of mammary ducts

- Infiltrating duct
- Solid and gland-forming
- Scirrhous
- Inflammatory
- Medullary
- Colloid or mucous
- Mucocoele-like lesion
- Signet ring type
- "Apocrine"
- Tubular
- Papillary

Intraductal carcinoma (in situ carcinoma of ducts)

- Solid type
- Comedo type
- Solid papillary carcinoma

Carcinoma of mammary lobules

- Infiltrating lobular carcinoma
- Lobular carcinoma in situ

Mixed types of carcinomas (ductal and lobular, ductal and colloid, etc)

Rare types of mammary carcinomas

- Spindle cell carcinoma
- Adenoid cystic carcinoma
- "Metaplastic" carcinoma
- Carcinoma mimicking giant cell tumor of bone
- Secretory (juvenile) carcinoma
- Other extremely rare types

In about 80% of mammary carcinomas, the diagnosis can be made in a secure fashion, based on the general cell features outlined above. In about 20% of mammary cancers, usually of the **well-differentiated types, the cancer cells** are smaller and their nuclei are more homogeneous. In such cases, a confident cytologic diagnosis of cancer based on needle aspirates may not always be possible. It is particularly advisable **to not make the cytologic diagnosis of mammary carcinoma in the presence of inflammation, except on overwhelming evidence.**

There are **significant differences in the appearance of the cancer cells, depending on the method used to process the smears. In air-dried, methanol-fixed smears processed with a hematologic stain**, the cells tend to be larger and the details of nuclear abnormalities, such as the distribution of chromatin and the presence of nucleoli, are difficult to assess. These smears have the **advantage of almost instantaneous availability**, and in most cases are adequate for diagnosis. In **alcohol-fixed, Papanicolaou-stained smears**, the cells are about 20% smaller but the nuclear details are much more visible. Several hours are required for processing of this material. In this text, many of the breast carcinomas are shown in both modes of processing, side by side, to allow for comparison (see Figs. 29-25, 29-26, 29-27, 29-28, 29-29, 29-30, 29-31 and 29-32).

Carcinomas of the Mammary Ducts

Infiltrating Duct Carcinoma: Solid and Gland-Forming Types

Histology

The solid and gland-forming types of infiltrating breast carcinoma are by far the most common varieties of breast cancer. The tumors may occur in any quadrant of the breast. The palpable tumors are firm, not movable, and composed of **sheets and strands of large cancer cells** infiltrating the stroma of the breast. **Gland formation** by tumor cells is common. A connective tissue reaction may render the tumors particularly hard to the touch, resulting in the **scirrous variant of duct cancer**. Some tumors that are occasionally diagnosed as **argyrophilic carcinomas** may **mimic carcinoids**, and may react positively with silver stain (hence the name) or stains documenting endocrine activity. However, the behavior of these tumors is typical of duct cancer. The tumors may be confined to the ducts as intraductal **carcinoma in situ (DCIS)** (see below).

Cytology

Infiltrating duct carcinomas usually have the classic cytologic presentation, as described above (Fig. 29-25). Other variants are shown in Figures 29-26 and 29-27. The large cancer cells may be approximately spherical, but are sometimes elongated or even columnar in configuration. The cells may be **predominantly dispersed, form large clusters, or mimic glandular structures**. Occasionally the cells are arranged in a **single file**, but this arrangement is more often seen in lobular carcinoma (see below). The **nuclei** are usually (but not always) **large, irregular, and coarsely granular**, and usually contain visible nucleoli of various sizes. It may be noted that **peripheral placement of the nuclei, mimicking large plasma cells, is common** in cells of duct carcinoma (see Figs. 29-26 and 29-28). **Mucus vacuoles** are also commonly seen in the cytoplasm of cancer cells, and usually have a **strongly positive reaction with mucicarmine**.

Figure 29-25 Basic cytologic pattern of mammary duct carcinoma. Comparison of Papanicolaou (A,C) and Diff-Quik (B,D) stains. A,B. Dispersed pattern. C,D. Cluster formation. Note the large abnormal nuclei in all smears.

Diagnostic difficulties may occur with exceptionally well differentiated tumors of **low nuclear grade** that may shed cells in sheets and show only slight nuclear enlargement. This may be observed in **tumors mimicking carcinoids** (Ni and Bibbo, 1994). In such cases, it may be extremely helpful to search for a few classic cancer cells and **mitotic activity**, and to pay close attention to nuclear abnormalities, such as nucleoli.

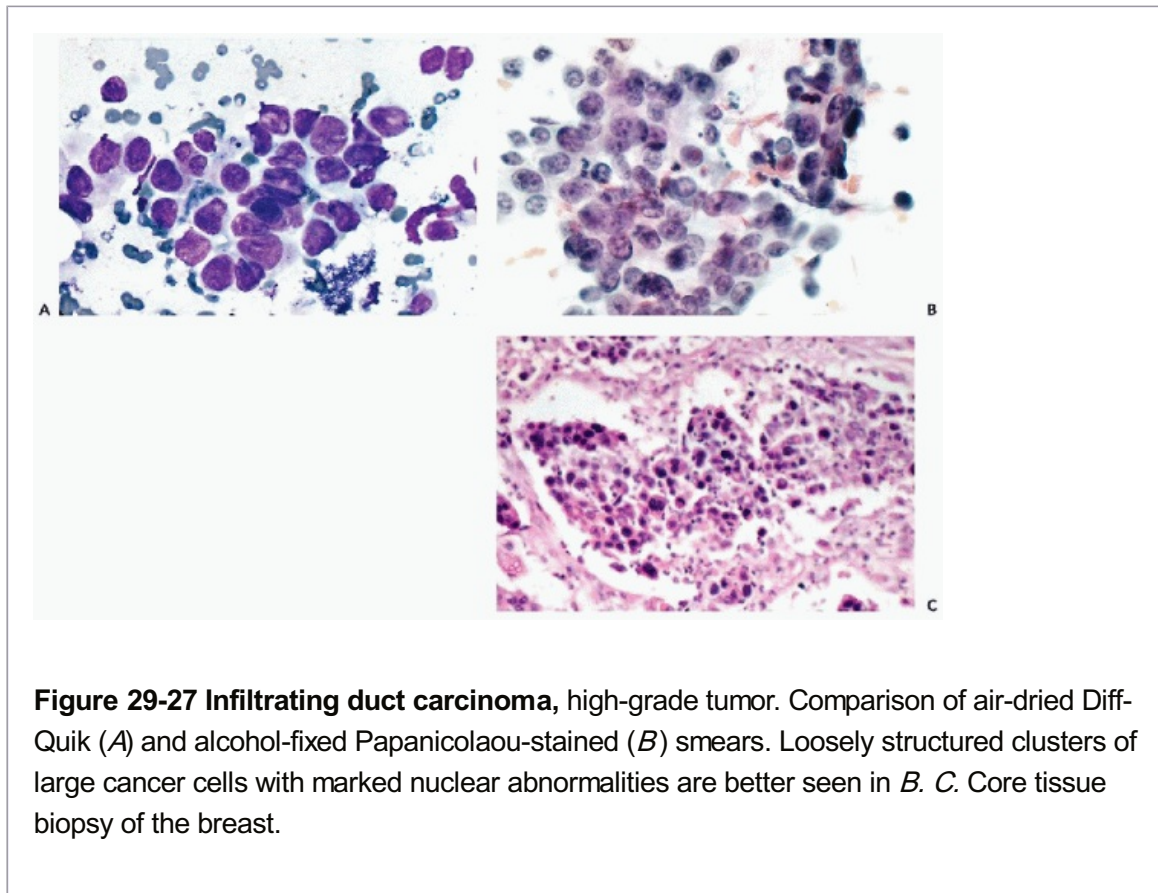

Figure 29-26 Duct carcinomas discovered by mammography. A. Smear from a 72-year-old patient. The large cancer cells are either approximately spherical or columnar. B. Tissue section from the same patient showing ductal carcinoma in situ. Elsewhere the tumor was invasive.

Scirrhous Variant of Duct Carcinoma

Because of marked fibrosis, the aspirate may yield only a **few cancer cells, usually with peripheral nuclei**. If this cancer cell population is not contaminated by benign cells, the

diagnosis may be made with reasonable confidence. **If, however, scanty abnormal cells are associated with benign epithelial cells, it is advisable to request a tissue biopsy.**

P.1107

Ductal Carcinoma In Situ

Histology

Depending on the size and number of the ducts involved, the tumors may be **palpable** or incidentally discovered by **mammography**, often because of the presence of microcalcifications.

Ductal carcinoma in situ is a form of breast cancer that is confined to ducts. It exhibits several patterns. The most common of these are the **solid** and **comedo** patterns (the latter shows necrosis in the center of the duct). Less common are the **micropapillary** and **apocrine** patterns (Lagios, 1990). Scott et al (1997) documented that diagnostic reproducibility among expert pathologists is higher for the common types and less satisfactory for the rare types.

Figure 29-28 *A.* Breast cancer cells with peripheral placement of nuclei, mimicking plasma cells. This is a common feature in breast cancer. *B.* Smear from a 61-year-old patient, obtained under stereotaxic guidance. The very large cancer cells are mainly of columnar shape. Their large nuclei are located at the periphery of the cells, which gives them a “plasmacytoid” appearance. (*B.*: Diff-Quik.)

Patchefsky et al (1989) documented that the probability of invasion is related to the type of intraductal lesion involved, with **comedo-type** DCIS forming larger lesions and being the most likely to progress to invasive cancer. Another

P.1108

feature studied by Patchefsky et al (1989) was **nuclear grading**, which is divided into three levels of abnormalities: **low, intermediate, and high**. Not surprisingly, tumors with high-grade nuclear abnormalities were comedo-type and solid DCIS, which are the lesions most likely to progress to invasive cancer. Dinkel et al (2000) attempted to correlate the type of **microcalcification in mammograms (linear, or finely or coarsely granular)** with the grade of DCIS. Although **linear calcifications were more likely to be associated with high-grade lesions**, the overall correlation was poor.

A rare and peculiar form of intraductal carcinoma is the **solid papillary carcinoma**, first identified by Maluf and Koerner (1995). These tumors occur mainly in elderly women and have a good prognosis. The tumors are composed of sheets of small cancer cells containing islands of connective tissue (presumably the papillary core of the tumor).

Some of the unusual features of these tumors are the endocrine differentiation of tumor cells and the presence of lakes of mucus. This intraductal tumor may be associated with invasive colloid carcinoma.

Cytology

It is a matter of considerable controversy whether ductal carcinoma in situ can be distinguished from invasive carcinoma in aspiration smears. In our opinion, the **cytologic distinction of intraductal carcinoma in situ from an invasive cancer is not reliable**. In its classic presentation, smears from high-grade ductal carcinoma in situ are composed of **spherical, rather compact clusters of large cancer cells with few dispersed cells** (Fig. 29-29). **In the comedo type, necrotic material may be present**. Lilleng and Hagmar (1992) noted that in aspiration smears, only the presence of fat infiltrated by cancer cells must be considered as definitive evidence of invasion. Thus, excision of the lesion is mandatory to **confirm the absence of invasion**. McKee et al (2001) suggested that the presence of myoepithelial (bipolar) cells is suggestive of noninfiltrating carcinoma; however, in our experience the difference between carcinoma in situ and infiltrating carcinoma **can only be established by careful examination of tissue evidence**. Pure intraductal carcinoma and intraductal carcinoma with invasion have the same cytologic presentation.

Figure 29-29 Infiltrating duct carcinoma masquerading as duct carcinoma in situ. *A.* Low-power view of a smear. Only compact clusters of cancer cells are seen. *B.* Higher-magnification view of one of the clusters. The cluster is compact and shows nuclei of very similar sizes. *C.* Ductal carcinoma in situ, adjacent to invasive carcinoma shown in *D.* (*B:* Diff-Quik stain.)

In a more recent study, conducted in Norway, Bofin et al (2004) attempted to separate benign intraductal hyperplasia from atypical intraductal hyperplasia, DCIS, and invasive duct cancer in aspiration smears. Although they performed an elaborate multinomial logistic regression analysis of 19 criteria, the authors were only able to reliably separate benign from malignant lesions. They were unable to separate atypical ductal hyperplasia from DCIS or invasive cancer.

P.1109

Atypical ductal hyperplasia had the same cytologic features as DCIS and invasive carcinoma, which strongly suggests that it is at least a precursor lesion of DCIS, and, even more likely, an early malignant lesion of mammary ducts of uncertain behavior.

Some of these lesions may be incidentally observed in ductal lavage (see the closing pages of this chapter). The histologic analysis of such lesions may also be controversial. Bofin et al (2004) confirmed that cytologic differentiation of atypical ductal hyperplasia from DCIS is exceedingly difficult to achieve.

A peculiar form of solid ductal carcinoma in situ is the **low-grade cribriform carcinoma**. Although these lesions are sometimes **bulky, they are rarely associated with invasive behavior**. Histologically, the lesions are of low nuclear grade and may show cytoplasmic evidence of endocrine activity. Lilleng et al (1992) described the aspiration cytology of three cases of this lesion, and pointed out the presence of **large, cohesive sheets of small malignant cells**, some with central gland-like structures with relatively few cancer cells occurring singly. The nuclei, although somewhat enlarged and hyperchromatic, were nearly identical and therefore of a very low grade. A similar case was described by Ayata and Wang (1999).

Experience with the cytologic presentation of the **rare types of DCIS**, such as the

micropapillary type, is very limited (Khurana et al, 1997).

The cytologic presentation of a few cases of **solid papillary carcinoma** was described by Boran et al (1998), Tse and Ma (2000), and Yin and Schinella (2002). The common finding was **dispersion of numerous but relatively small tumor cells** with somewhat **enlarged but otherwise unremarkable nuclei**. **Plasmacytoid tumor cells** with peripheral nuclei were noted.

Obviously, it is difficult to recognize and cytologically classify the rare types of intraductal carcinomas at least in part because of the very limited experience with these lesions.

Inflammatory Carcinoma

In this important and aggressive form of mammary carcinoma, **duct cancer cells infiltrate the lymphatics of the skin, rendering the breast swollen, red, and hot to the touch, thus mimicking an inflammatory process**. Aspiration biopsy is the ideal means of diagnosing this disease. Sanchez and Stahl (1996) recommend the use of a small-caliber needle **introduced into the breast parallel to skin surface**. In the aspirate, abundant cancer cells of various sizes can be readily recognized. Similar observations were reported by Akhtar (1996). A tumor with a previously hopeless prognosis can now be aggressively treated with chemotherapy, with much better survival.

Medullary Carcinoma

Histology

These fleshy tumors are often circumscribed, may **mimic grossly a fibroadenoma**, and are usually of a **softer consistency than classic duct carcinomas**. The tumors are composed of **large sheets of very large cancer cells with conspicuous nuclear abnormalities**. A **lymphoid component** at the periphery, and within the tumor itself, is often present (**medullary carcinoma with lymphoid stroma**). The tumors appear to have a better prognosis than the conventional duct cancers.

Cytology

The aspirates of the tumor are rich in **large, undifferentiated cancer cells, with irregular coarsely granular nuclei and often very large nucleoli**, arranged singly and in loose clusters (Fig. 29-30). Abnormal mitotic figures are sometimes conspicuous. The presence of lymphocytes is mandatory for recognition of tumor type. As discussed in reference to breast changes in pregnancy, Zajicek pointed out that certain **similarities** may sometimes exist between the **smear pattern of cancer cells** derived from this tumor type and **cells derived from lactating breast**. The degree of cellular and nuclear abnormality in medullary carcinoma is significantly greater than that observed in cells derived from a lactating breast. Still, this observation calls attention to the **dangers of cytologically diagnosing mammary carcinoma during pregnancy and lactation**.

Colloid (Mucinous) Carcinoma

Histology

Colloid tumors, which usually occur in elderly women and often achieve a **large size**, are characterized by abundant **lakes of mucus surrounding clusters of cancer cells**. In some tumors, the search for cancer cells may be difficult because of the **dominance of mucus**. The

prognosis for this type of breast cancer is significantly better than that for ordinary duct carcinoma. A very rare variant of this tumor, **true signet-ring carcinoma of the breast (which is similar to intestinal tumors)**, has a poor prognosis (Sanchez and Stahl, 1996).

Cytology

The characteristic features of this tumor are abundant mucus forming the background of the smear, and dispersed clusters of cancer cells. The clusters, which are usually composed of several dozens of cells, are **cohesive and show only slight nuclear abnormalities, such as nuclear enlargement and small nucleoli**. Small clusters and single isolated cancer cells may be observed in some tumors. The diagnosis is based on the presence of **mucus bathing the clusters** and is easier to obtain in **air-dried smears stained with hematologic stains**, wherein the **mucus stains pink, red, or purple**. In fixed **Papanicolaou-stained smears**, the **mucus appears as a gray-staining amorphous substance** in the background of the smear, and a positive **mucicarmine stain** may be needed to confirm the diagnosis (Fig. 29-31). Unless close attention is paid to the presence of mucus, this type of mammary carcinoma may be difficult to diagnose because of the relatively trivial nuclear abnormalities in the cohesive clusters of cancer cells. The diagnosis requires a close correlation with clinical findings.

A rare **true signet-ring carcinoma of the breast with poor prognosis shows large cancer cells with vacuolated**

P.1110

cytoplasm (Fig. 29-32A,B). These cells must be differentiated from similar but **much smaller cancer cells that occur in lobular carcinoma**, as described below (Kamiya et al, 1998).

Figure 29-30 Medullary carcinoma. A,B. Clusters of large cancer cells with scattered small, mature lymphocytes in the background. The pictures illustrate the differences in morphologic presentation between an air-dried Diff-Quik-stained smear (A) and fixed Pap-stained material (B). C. Highpower view of a smear from a similar case, showing a tripolar mitosis. D. Histologic aspects of the lesion showing solid clusters of cancer cells and a lymphocytic component.

Mucocele-Like Lesion

An important, although infrequent, point of **differential diagnosis** of colloid carcinoma is **mucocele-like lesions**, which were first described by Rosen (1986) as a mucusfilled benign cyst resembling the mucoceles of other organs. Subsequently, Hamele-Bena and Rosen (1996) reported that a **malignant variant** of this lesion may occur, sometimes in the form of a ductal carcinoma and sometimes as a cancer occurring within the cyst.

Cytology

There are several reports in the literature describing the relatively **minor differences in cytology between the benign and malignant variants of the mucocele-like lesion and colloid carcinoma** (Fanning et al, 1990; Bhargava, 1991; Sneige, 1993; Wong and Wan, 2000). Both types of lesions are characterized by the presence of **abundant mucus**. The colloid carcinoma usually has a much larger cell population than the mucocele-like lesion, whether benign or malignant. In two cases of the malignant mucocele-like lesion, Wong and Wan (2000) observed cell clusters with minimally enlarged nuclei but no clear evidence of malignant transformation. It is evident that **all breast lesions containing abundant mucus should be excised for histologic examination because aspiration cytology of these lesions may be highly misleading**.

“Apocrine” Carcinoma

There is considerable doubt as to whether duct cancers of this type deserve a separate classification. Still, in practice, one is confronted every once in a while with a mammary carcinoma composed of **large cancer cells with eosinophilic, granular cytoplasm**, resembling benign apocrine cells (Fig. 29-32C,D). It is sometimes difficult to differentiate benign from malignant apocrine cells, inasmuch as the benign apocrine cells may display large, usually dark nuclei and nucleoli of substantial sizes, whereas **in apocrine carcinoma the nuclei are large and contain sizable, often multiple nucleoli**. There is also a significant **variability in the sizes of the cancer cells and their nuclei and nucleoli**. The smears from carcinomas usually show at least some cancer cells of the classic type (Koss et al, 1992). Further, the **clinical presentation** of apocrine carcinoma is that of breast cancer, whereas benign apocrine cells usually occur in clinically benign lesions and in younger women. Still, in

P.1111

the case of doubt, a tissue biopsy should be requested for confirmation of the diagnosis. An unusual and very rare variant of apocrine carcinoma is the **myoblastomatoid carcinoma**. The cytology of this rare tumor was described by Cohen et al (1997) as showing cohesive clusters of atypical cells with granular and finely vacuolated (“foamy”) cytoplasm.

Figure 29-31 Colloid (mucinous) carcinoma. *A.* Typical cohesive cluster of cancer cells with only slight nuclear abnormalities. *B,C.* Mucicarmine stain to document the presence of mucus bathing the clusters. *D.* Tissue section showing the histologic bases of the cytologic findings.

Tubular Carcinoma

Histology

These relatively uncommon tumors are composed of **well differentiated, sinuous, open tubules infiltrating the stroma and fat of the breast** (Fig. 29-33D). With an experienced eye, the diagnosis can be made under low microscope power because the pattern of growth of this lesion is so characteristic, whereas the abnormalities of cancer cells are usually trivial. Small tubular carcinomas are detected by mammography with surprisingly high frequency.

Cytology

The cytologic diagnosis of tubular carcinoma is one of the most difficult tasks in aspiration of the breast. The tumor cells form **cohesive, three-dimensional, complex, often branching and angulated tubular clusters of epithelial cells**, resembling somewhat the structures sometimes seen in fibroadenoma (see Fig. 29-19B). The diagnosis of carcinoma can be established if the **tubular structures are surrounded by fat** in the background of the smears, corresponding to the tumor tubules infiltrating fat in histologic sections. The **nuclear abnormalities in tubular carcinoma are relatively trivial**: the spherical nuclei are enlarged but not hyperchromatic, and contain **visible, small nucleoli**. This classic and diagnostic presentation of tubular carcinoma is unfortunately not always seen. In other cases, the tubular structures may be less complex and may **mimic to perfection a fibroadenoma** (Fig. 29-33A,B). In one such case, the **presence of myoepithelial cells made it impossible to diagnosis carcinoma** (Fig. 29-33C) (Koss et al, 1992). In a study involving 34 such cases, Bondeson and Lindholm (1990) experienced diagnostic difficulties in about 50% of the cases. Dawson et al (1994) described their experience with 24 such lesions, mostly detected by mammography, **and failed to recognize it in all but one suspicious case**. These diagnostic difficulties were also emphasized by Fischler et al (1994). Clearly, the clinical and mammographic presentation of the

lesion is very important in debatable cases, and all suspicious lesions should be excised.

De la Torre et al (1994) compared the cytologic presentation of 33 tubular carcinomas with that of 12 **radial scars**, lesions thought to be precursors of breast cancer. The **mammographic presentation** of tubular carcinomas and radial

P.1112

scars may be similar as a central point of convergence of linear thickenings (scars). The aspirates of radial scars also contained **angular tubular structures, invariably accompanied by myoepithelial cells**. Thus, there are great radiologic and cytologic similarities between the two lesions that require histologic clarification. It is also of note that only 19 of 33 tubular carcinomas in De la Torre et al's (1994) important study were unequivocally recognized as malignant, which usually was the case when the tubular carcinomas were **accompanied by duct cancers** (12 of 33 cases). In 10 cases, a diagnosis of "atypical" (four cases) or "suspicious" (six cases) was established. In four cases of tubular carcinoma, the lesion was not recognized at all because of the presence of myoepithelial cells, as discussed above.

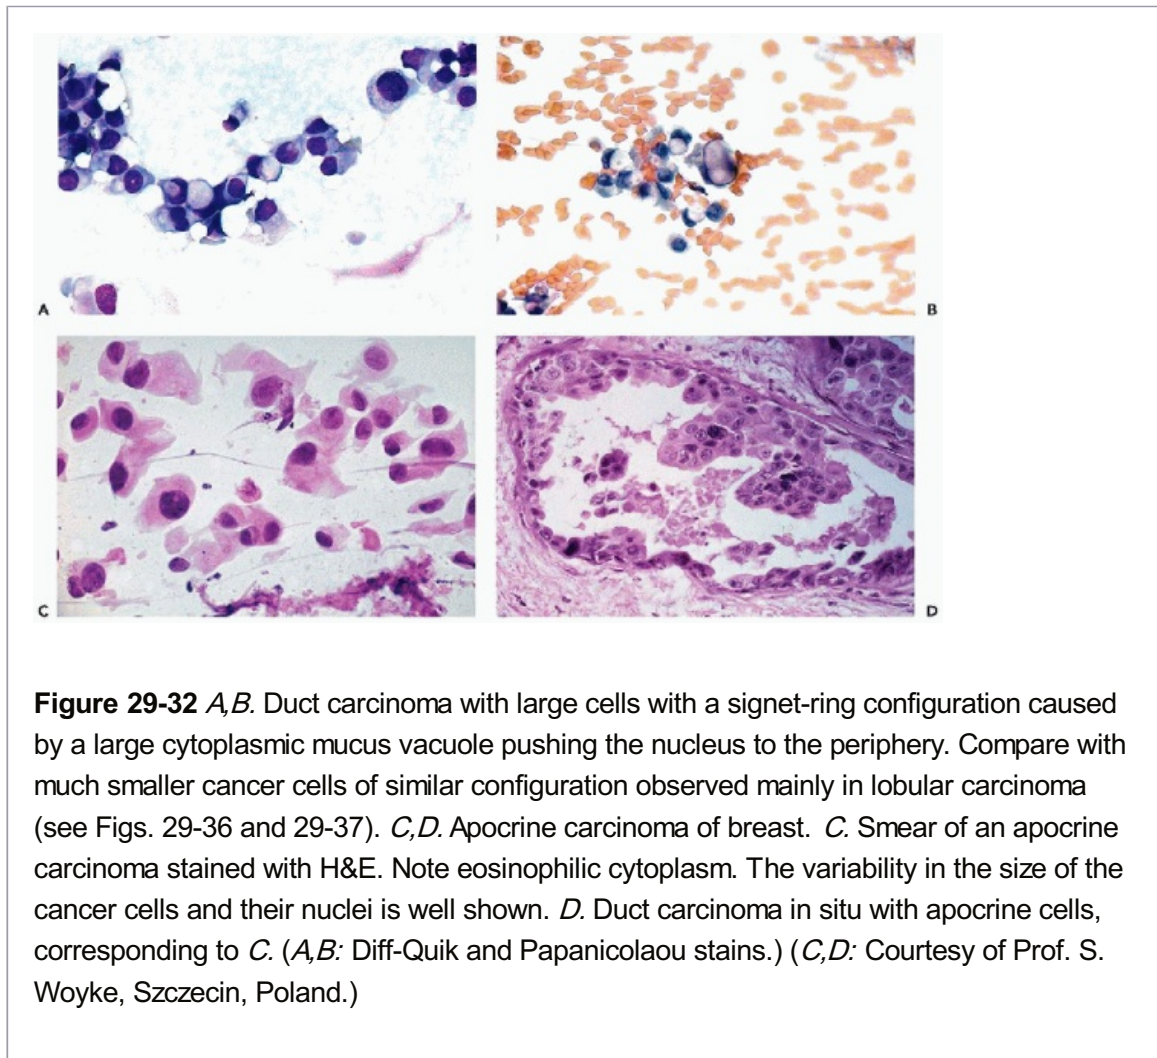

Figure 29-32 A,B. Duct carcinoma with large cells with a signet-ring configuration caused by a large cytoplasmic mucus vacuole pushing the nucleus to the periphery. Compare with much smaller cancer cells of similar configuration observed mainly in lobular carcinoma (see Figs. 29-36 and 29-37). C,D. Apocrine carcinoma of breast. C. Smear of an apocrine carcinoma stained with H&E. Note eosinophilic cytoplasm. The variability in the size of the cancer cells and their nuclei is well shown. D. Duct carcinoma in situ with apocrine cells, corresponding to C. (A,B: Diff-Quik and Papanicolaou stains.) (C,D: Courtesy of Prof. S. Woyke, Szczecin, Poland.)

Papillary Carcinoma

The difficulties in the differential diagnosis between intraductal papilloma and intraductal papillary carcinoma are discussed above. In aspiration smears, the abnormalities are very difficult to recognize because the cells show virtually no nuclear abnormalities (Fig. 29-34). For comments on "**solid papillary carcinoma**," see above. Another variant, termed **invasive**

micropapillary carcinoma, was described by Khurana et al (1997). It is doubtful that these variants could be recognized on aspiration smears.

Carcinomas of the Breast Lobules

Infiltrating Lobular Carcinomas

As Li et al (2003a) reported, the incidence rates of these tumors are increasing, while the incidence of ductal cancers remained unchanged from 1987 to 1999.

Histology

Infiltrating lobular carcinomas are characterized by **strings of small cancer cells** arranged in single files that are separated from each other by **bands of connective tissue** (Fig. 29-35). Clusters of small cancer cells are usually scattered throughout the tumor, sometimes forming glands. In some cases, **foci of lobular carcinoma in situ** may be observed. On close inspection, the small cancer cells often display peripheral nuclei and **small, mucin-containing cytoplasmic vacuoles**, which are better seen in aspirated material. A **mucicarmine stain or periodic acid Schiff (PAS) stain**, which reveals the cytoplasmic vacuoles, is often helpful for accurately classifying the tumor. The edges of lobular

P.1113

carcinoma virtually always infiltrate the stroma of the breast. Occasionally, **cancerous ducts**, which are similar to those observed in ductal carcinoma, are present. The **prognosis** for infiltrating lobular carcinoma is similar to that for infiltrating duct carcinoma.

Figure 29-33 Tubular carcinoma. *A.* Complex cluster of small cells mimicking epithelial cells in a fibroadenoma (see also Figs. 29-17 and 29-18). *B.* Another example of tubular carcinoma. Gland-like spaces are surrounded by small cancer cells (see also Figure 29-19B). *C.* The same case as in *B.* Bipolar myoepithelial cells were present in the background of the smear, rendering the diagnosis of cancer vs. fibroadenoma virtually impossible. *D.* Tissue section corresponding to *A.* Note the infiltration of fat by tubular tumor structures.

Figure 29-34 Papillary carcinoma. *A.* Aspiration smear showing a cluster of cells with enlarged but clear nuclei of equal sizes and tiny nucleoli, forming a gland-like structure. *B.* Corresponding tissue section showing invasive papillary carcinoma.

Cytology

Some of these tumors are **difficult to aspirate** because there is **considerable fibrosis**, which results in diagnostic problems caused by scanty evidence of cancer. In most cases, a population of **small, fairly monotonous cancer cells** is

P.1114

observed, with at least some cells showing **cytoplasmic vacuoles** on close inspection (Fig. 29-36). The cells are either dispersed or form **clusters and single files**. The nuclei, often granular and of similar sizes, are usually smaller than those of duct cancer. The coarse granularity of chromatin, which is often observed in duct carcinoma, is rarely observed.

Figure 29-35 Lobular carcinoma. Low- and high-power views of tissue sections of an infiltrating lobular carcinoma. *A.* Concentric circles of small cancer cells in single file. *B.* The small size of the cancer cells is evident.

In fixed material, a characteristic feature of lobular carcinomas (primary or metastatic) is the presence of **cytoplasmic vacuoles with a central condensation of mucus** in small cancer cells (Fig. 29-37A,B). This is best demonstrated with mucicarmine stain. In air-dried May-Grünwald-Giemsa (MGG)-stained smears, the **mucus stains a violet-reddish color**. The terms **magenta cells** and **target cells** have been used to describe this phenomenon (Fig. 29-37C).

This feature is less visible in Diff-Quik-stained smears. Occasionally, such mucus inclusions may also be observed in ductal carcinomas, although the cancer cells are usually much larger.

It has been claimed by de las Morenas et al (1995) that the only **objective differences between ductal and lobular carcinomas** are the size of the nuclei (smaller in lobular carcinoma) and the granularity of chromatin (more frequent in duct cancer). These authors failed to study the cytoplasmic features that often clearly distinguish the two types of mammary cancers. To be sure, **coexisting ductal and lobular carcinomas** are fairly common. In such cases, both tumor types should be reported.

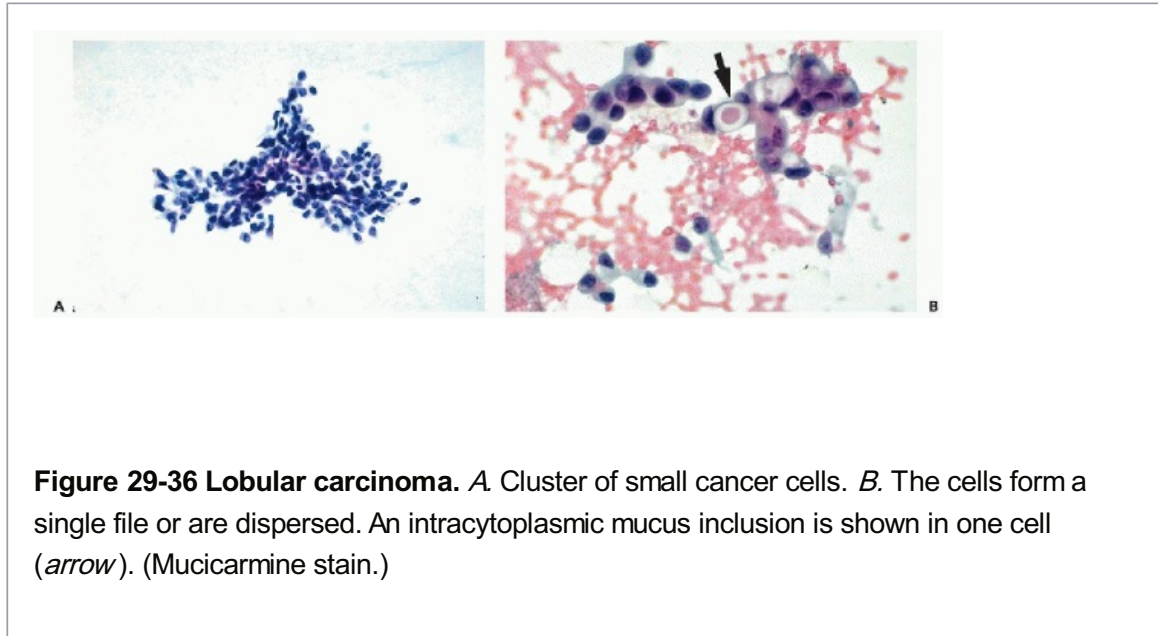

Figure 29-36 Lobular carcinoma. *A.* Cluster of small cancer cells. *B.* The cells form a single file or are dispersed. An intracytoplasmic mucus inclusion is shown in one cell (*arrow*). (Mucicarmine stain.)

In tissue sections, one may document the differences between ductal and lobular carcinoma by immunostaining for cytokeratin 8 and the **adhesion molecule E-cadherin**. The latter is expressed by ductal, but not lobular, carcinomas (Lehr et al, 2000), an observation that has also been extended to lobular carcinoma in situ (Goldstein et al, 2001). There are as yet no comparative studies in aspirated cell samples.

Variants of Lobular Carcinoma

Vdovenko et al (2001) described a case of lobular carcinoma with **prominent, coarse cytoplasmic granules** representing phagosomes on electron microscopy. Dabbs et al (1994) and Auger and Huttner (1997) described a **pleomorphic variant of infiltrating lobular carcinoma** as showing greater cellularity and more pleomorphic nuclei. A so-called

P.1115

solid variant of this tumor, characterized by dissociated cancer cells, has also been described (Antoniades and Spector, 1989; Fleming and Tang, 1994). The very rare **tubulolobular carcinoma**, which combines features of both lobular and tubular carcinomas, was described by Boppana et al (1996).

Figure 29-37 Lobular carcinoma. The cytoplasmic mucus inclusions with a central dot (target cells) are well shown with mucicarmine stain (A), high magnification (B), and May-Grunwald-Giemsa (MGG) stain (C). The term *magenta cells* is sometimes used to describe the MGG-stained cells. (C: Courtesy of Dr. B.-M. Ljung, San Francisco, CA.)

Lobular Carcinoma In Situ

Clinical Presentation and Histology

The lesion known as lobular carcinoma in situ was so named many years ago by my former chiefs, Foote and Stewart (1941, 1946) of Memorial-Sloan Kettering Cancer Center, who described it as a **precursor lesion of mammary carcinoma**. The microscopic lesions were incidentally observed in breast biopsies, and the examined women were not treated. During a follow-up study of over 20 years, it was documented that women with this lesion in the breast were at a **high risk for breast cancer** that could develop in the same or the contralateral breast (Fig. 29-38). Subsequent studies have confirmed that lobular carcinoma in situ is **often bilateral** and is a risk factor for invasive cancer (Rosen et al, 1978). However, the chances of cancer were considered remote, and some observers rechristened the lesion as **atypical lobular hyperplasia**. However, recent comparative genomic hybridization studies have documented **strong genetic similarities** (e.g., loss of chromosome 16q) between infiltrating and in situ lobular carcinomas (Etzell et al, 2001). Thus, the **malignant nature of this lesion is no longer in doubt**. At the time of this writing (2004), most of these lesions are discovered by microcalcifications observed in mammography. The choice for the patient is whether to have the lesion removed or to receive tamoxifen therapy in the hope that the lesion will not progress.

The lesion consists of **enlarged lobules** filled with **cells that are larger than normal, with enlarged nuclei and sometimes vacuolated cytoplasm** (Fig. 29-38). Small **deposits of calcified material** are often observed within the lobules, accounting for some of the **microcalcifications** observed in mammograms.

Cytology

The **diagnosis of lobular carcinoma in situ is very rarely made on aspirates**. The finding

of these small lesions is usually incidental. We have observed a few such cases, one of which **originated in a fibroadenoma**. The cell population has the **same features as those of infiltrating lobular carcinoma**. In the case that originated in a fibroadenoma, we also observed **myoepithelial cells** adjacent to cancer cells (Fig. 29-39). In other cases, lobular carcinoma in situ was an incidental finding adjacent to infiltrating lobular carcinoma or duct carcinoma in situ.

Table 29-4 summarizes the cytologic features of most common types of mammary carcinoma.

Rare Types of Mammary Carcinoma

Lipid-Secreting Carcinoma

Lipid-secreting carcinoma is a rare variant of duct carcinoma, first described by Aboumrad et al (1963), that can be recognized in smears. In histologic sections, the cancer cells secrete lipid in the form of **cytoplasmic vacuoles** of various sizes that give a positive reaction with fat stains. The cytology of a few such cases has been described (Aida et al, 1993; Insabato et al, 1993). **Cancer cells with single or multiple cytoplasmic vacuoles of various sizes** have been observed in aspiration smears. The true nature of the vacuoles must be demonstrated with a positive fat stain.

TABLE 29-4 PRINCIPAL CYTOLOGIC FEATURES OF COMMON TYPES OF CARCINOMAS OF THE FEMALE BREAST IN FNA

	Size and configuration of malignant cells	Special features
Duct carcinoma	Large cells in clusters or dispersed	Nuclear grades vary
Lobular carcinoma	Smaller cells often in single file	Cytoplasmic mucous inclusions ("target cells," "magenta cells")★
Medullary carcinoma	Large dispersed	Lymphocytic background
Colloid carcinoma	Large, tightly packed in clusters	Abundant mucus in background
Tubular carcinoma	Convolutd, complex tubular structures composed of small	If myoepithelial cells are present, the diagnosis cannot be made

cells

★ May occasionally occur in ductal carcinoma

Mammary Carcinoma With Osteoclast-Like Giant Cells

Mammary carcinomas contain **large giant-cells with small nuclei that mimic to perfection normal osteoclasts**. These cells may be observed in aspiration smears, and were recently observed in a very well differentiated cancer (Fig. 29-40). We have observed such cells in a poorly differentiated metaplastic carcinoma (Koss et al, 1992). Gupta et al (1991, 1992b, 1996a) described tumors with **epithelial giant cells** (one of which occurred in a pregnant patient) that probably represented the same or a similar entity.

Figure 29-40 Mammary carcinoma with osteoclast-like giant cells in an 89-year-old patient. *A.* Aspiration smear. Large, pale, multinucleated giant cells with small, even nuclei mimicking osteoclasts are adjacent to cohesive clusters of well differentiated cancer cells. *B.* Tissue section of the same case. Well differentiated adenocarcinoma with giant cells apparently formed in the fibrous stroma of the tumor.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma, which is rare in the breast, shares certain morphologic and ultrastructural features with identical tumors that are common in the salivary glands (Koss et al, 1970). The cytology of the tumor is described at length in Chapter 32. The cytology of cases occurring in the breast was described by Zaloudek et al (1984), Gáled-Placed and Garcia-Ureta (1992), and Stanley et al (1993c).

Secretory Carcinoma (Juvenile Carcinoma)

Secretory carcinoma (juvenile carcinoma) is an uncommon tumor that was first observed as a palpable breast mass in children, and was described as being similar to mammary

P.1118

cancer occurring in female dogs (McDivitt and Stewart, 1966). The malignant nature of the tumor was limited to an occasional metastasis to the axillary lymph node, but the prognosis was excellent. It has been subsequently shown that the tumor may also be observed in young adults, with a similarly good prognosis (Tavassoli and Norris, 1980).

The histologic structure of this tumor is peculiar, inasmuch as it consists of **cystic papillary and tubular structures composed of large, vacuolated epithelial cells lodged within a loosely structured stroma**. Secretory eosinophilic material, which stains positive with the PAS reagent, is also found in the stroma of the tumor.

Cytology

There have been several reports regarding the cytologic presentation of secretory carcinoma in aspirates from the breasts of children and young adults (Akhtar et al, 1983; d'Amore et al, 1986). Secretory carcinoma is characterized by the presence of **large vacuolated cells with large nuclei and occasional nucleoli**, and deposits of **secretory material in the background of the smear**. Vesoulis and Kashkari (1998) compared the cytologic findings with those in a lactating breast. The similarities may indeed be troubling if the tumor is observed in women of childbearing age, rather than in a child. However, the clinical and gross appearance of the tumor does not correspond to that of a lactating breast.

Squamous Carcinoma

Primary squamous carcinoma of the breast is extremely rare. These tumors may **form a cystic cavity**, as do squamous carcinomas in other organs, which may cause a serious diagnostic mishap on aspiration biopsy. In cavitating tumors, the aspirated **fluid is either acellular or may contain squamous debris that cannot possibly be recognized as cancer** and is diagnosed as **fluid from a cyst**. When the lesion occurs in a young patient, as in a case seen by us, the delay in diagnosis may be fatal. The differential diagnosis also includes **subareolar abscesses**, as described above (see Fig. 29-8). However, whereas subareolar abscesses are always painful, squamous cancer presents as an indolent lump. In solid carcinomas of this type, **squamous cancer cells** are observed in aspirates. For a description of these cells, see Chapters 11, 20, and 21.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas are common in the salivary glands, but they may also occur in the breast. Sporadic cases of low- and high-grade tumors have been described (Pettinato et al, 1989; Krigman et al, 1996). The cytology of the breast aspirates is similar to that of tumors of the salivary glands (see Chap. 32).

Small-Cell Carcinoma

Small-cell carcinomas are exceedingly rare malignant tumors of the **female and male** breast. They resemble **oat cell carcinomas** of the lung, and are often associated with either ductal or lobular carcinomas (for a summary see Shin et al, 2000). In two such cases, Hoang et al (2001) observed **molecular features** shared by duct cell carcinoma of the breast and oat cell carcinoma of the lung. Sebenik et al (1998) described the cytologic findings in a breast aspirate from an elderly woman as being very similar to pulmonary oat cell carcinoma (see Chap. 20). **Molding of small cancer cells** was noted, as was the presence of **cytoplasmic fragments that were similar to lymphoglandular bodies**, which are commonly observed in malignant lymphoma (see Chap. 31).

We observed a case of **occult** small-cell carcinoma of the breast with liver metastases. The cytology mimicked to perfection other small-cell tumors, and origin in the lung was first suggested. However, there was no evidence of lung cancer, and a further search disclosed a breast lesion 2 cm in diameter (Fig. 29-41). In Chapter 26 we describe a case of **metastatic**

basaloid mammary carcinoma, also composed of small cells (see Fig. 26-30).

Spindle Cell Carcinoma

It may be argued whether this uncommon entity is a variant of duct carcinoma, a metaplastic carcinoma, or a fibrosarcoma masquerading as a carcinoma. An example of this rare tumor is shown in Figure 29-42. The tumor is composed of sheets of spindle cells. This make-up is reflected in smears. A positive immunostain for keratin is helpful in classifying the tumor as a carcinoma.

Metaplastic Carcinoma

These highly aggressive malignant tumors **combine the features of a carcinoma with those of a well differentiated sarcoma, such as lipo-, osteo-, and chondrosarcoma or well differentiated fibrosarcoma** (Sneige et al, 2001). The cytologic features of such rare tumors have been described elsewhere (Koss et al, 1992) and are being sporadically reported by others. The principal point in the diagnosis of such tumors is the **recognition of two or more populations of malignant cells**. This can be performed only on excellent samples that are representative of the tumor. Johnson and Kini (1996) reported 10 such cases. There was a preoperative accurate diagnosis in five of the cases, and in two of them the clinical presentation was that of an **inflammatory carcinoma**. Similar observations were reported by Nogueira et al (1998), who diagnosed a mammary carcinoma in six of nine cases, and suggested that malignant cystosarcoma phyllodes were present in two patients.

Cystic Hypersecretory Ductal Carcinoma

Cystic hypersecretory ductal carcinoma is a very rare tumor of the breast that was first described by Rosen and Scott (1984). The lesion, which may achieve a very large size, mimics benign cysts. **Histologically**, it consists of **large cystic spaces filled with a colloid-like substance**. Although the cysts are predominantly lined by flattened cells of uncertain nature, parts of the lining and the adjacent cyst wall contain **duct carcinoma** (in situ or invasive) with a papillary or cribriform pattern.

The **cytology** of these lesions has been discussed in a few case reports (Colandrea et al, 1988; Lee et al, 1999; Kim et al, 1999). Schmitt and Tani (2000) reported a case with a false-negative diagnosis, and summarized the published experience. The **diagnosis is size-dependent**. The only case in which the tumor was recognized as malignant on initial aspiration was reported by Lee et al (1999), in a study involving a patient with a small lesion (2 cm in diameter). In all other cases with large lesions (some up to 8 cm in diameter), the primary diagnosis was that of cyst content. Schmitt and Tani (2000) stressed that the finding of **large deposits of colloid-like substance** in aspirated material should alert the observer that the relatively **sparse and innocuous-appearing cluster of epithelial cells** may represent a well differentiated duct carcinoma. This tumor must also be differentiated from the much more common **colloid carcinoma** and the equally rare **mucocoele-like lesion**, wherein the background of the smears contains mucus (see above).

P.1120

Malignant Intraductal Myoepithelioma

Malignant intraductal myoepithelioma was first described by Erlandson and Rosen (1982). This tumor **mimics** an **intraductal and invasive duct carcinoma**, but is composed of **small spindly cells** that under electron microscopy and cytochemistry share the characteristics of epithelial and smooth muscle cells. Tamai et al (1994) described and illustrated the cytologic and histologic findings in a case of this very rare disorder in an elderly woman. **Small spindly cells** with somewhat enlarged nuclei forming loosely structured bundles were observed in

smears. The identity of the cells was established by a positive cytoplasmic reaction with **alpha smooth muscle actin**.

Other Extremely Rare Carcinomas

A case of **lymphoepithelioma-like carcinoma of the breast** was described by Naidoo and Chetty (2001). For a description of the cytologic presentation of these tumors, see Chapter 21.

The cytologic presentation of very **rare variants of duct carcinoma**, such as **glycogen-rich (clear cell) carcinoma** (Kern and Andera, 1997), **sarcomatoid carcinoma** (Straathof et al, 1997), and **fibromatosis-like carcinoma** (Sneige et al, 2001), has been reported. It is doubtful that the specific type of these exceptional cancers can be established on aspirates.

Table 29-5 summarizes some of the uncommon malignant lesions of the breast.

Carcinoma of the Breast in Pregnancy

Carcinoma of the breast during pregnancy is an uncommon event that may cause substantial diagnostic difficulties in FNA. Gupta et al (1992c) described four such cases, one of which was a carcinoma with pleomorphic giant cells. The reason for the diagnostic difficulty is that the cytologic pattern of the **normal lactating breast may mimic carcinoma** because of the presence of **large nucleoli in acinar cells** (see above). Therefore, other criteria must be applied, such as **variability in cell and nuclear sizes**, and **hyperchromatic irregular nuclei**. An example is shown in Figure 29-43.

In general, one should exercise extreme caution in establishing a cytologic diagnosis of carcinoma in a pregnant woman.

Breast Cancer in Unusual Circumstances

Breast cancer cells were observed by us in the **contents of a Swan-Ganz catheter** in a 38-year-old woman with disseminated mammary carcinoma. In another patient, aspiration of a **paravertebral mass** led to a diagnosis of mammary carcinoma. Azuma et al (1997) reported a case of mammary carcinoma occurring in **aberrant breast tissue** in the axilla.

SARCOMAS

Except for **malignant cystosarcoma phyllodes** (discussed above), primary sarcomas of the breast are extremely rare. Sporadic cases of primary **fibrosarcoma**, **liposarcoma**,

P.1121

stromal sarcoma, **angiosarcoma**, **malignant lymphoma**, and **granulocytic sarcoma** have been described. Most sarcomas occur in elderly women. A detailed analysis of their histologic presentation is beyond the scope of this book.

Figure 29-43 Mammary duct carcinoma in a pregnant woman, age 38. Two aspects of

the aspiration smear showing a high-grade carcinoma with nuclear changes much greater than those observed in pregnancy (see Fig. 29-21).

From the **cytologic point of view**, these cases have in common an unusual population of malignant cells. **Elongated, spindly malignant cells** occur in **stromal sarcomas, fibrosarcomas, angiosarcomas, and the exceedingly rare leiomyosarcomas**, but may also be seen in spindle cell carcinoma (see above). It is of note that sometimes even low-grade stromal sarcomas with relatively benign-looking spindly component cells may metastasize to distal organs (Fig. 29-44). Gorczyca et al (1992) reported two cases of **fibrosarcoma**. Foust and Berry (1994) described a case of **liposarcoma**, characterized by fat cells of variable sizes with abnormal nuclei. Liposarcoma as a component of malignant cystosarcoma phyllodes was described by Lee et al (1998). Layfield (1997) reported a case of **postradiation angiosarcoma** (Stewart-Treves syndrome) involving the breast.

Figure 29-44 Stromal sarcoma of breast metastatic to lung. *A.* Aspiration smear of the metastatic lung lesion showing dispersed spindly cells with comma-shaped but not significantly abnormal nuclei and mucoid stroma. *B.* Histologic appearance of the primary lesion composed of bundles of spindly cells with abundant matrix.

Malignant Lymphomas

There have been several reports of malignant lymphomas, some primary and some metastatic to the breast. Pettinato et al (1991) and Gorczyca et al (1992) each described a case of a primary **high-grade lymphoma**. Corrigan et al (1990) reported a case of **recurrent Hodgkin's disease** that presented as a breast nodule in a young girl. Domchek et al (2002) described a large series of 73 patients with lymphomas involving breast. Thirty-two of these patients had primary disease, and the remainder had recurrent disseminated disease. Nearly all of the patients had palpable masses. Most of the primary breast lymphomas were of low grade. The cytologic presentation of these cases was similar to that observed in lymph nodes (see Chap. 31).

Several years ago we observed a breast tumor in a middleaged woman that was classified as **lymphocytoma of the breast**. Today, however, it would likely be classified as a **low-grade malignant lymphoma**. The lesion recurred several times over a period of 10 years after treatment by surgery

and radiotherapy. The patient ultimately died of a pulmonary carcinoma, which was unrelated to the breast lesion but perhaps was related to the radiotherapy. Several aspirates of the breast, obtained during the course of her disease, showed a fairly **monotonous population of lymphocytes**.

Hummel et al (1999) reported a very rare case of lymphoid hyperplasia with massive sinus histiocytosis (**Rosai-Dorfman disease**) in the breast of a 52-year-old woman. The aspiration smears contained a mixed population of cells, including clusters of macrophages and lymphocytic cells in various stages of maturation.

An important point in the differential diagnosis of a lymphoma is an **intramammary lymph node**. Such lymph nodes, which are usually located in the tail of the breast, may become hyperplastic and palpable, and mimic clinically mammary carcinoma. Aspiration cytology usually discloses a mixed population of lymphocytes (Fig. 29-45). Surgical removal of the node may still be necessary to rule out malignant lymphoma.

Surprisingly, the tumorous form of chronic myelogenous leukemia, known as **granulocytic sarcoma or chloroma**, has been repeatedly observed in the breast as the primary site. Ngu et al (2001) collected 18 reported cases, including those of Pettinato et al (1988), Barker (1998), and Liu et al (1999). Chloroma can be recognized because of the presence of **mature myeloid cells that can be analyzed further by immunocytochemistry and flow cytometry**, as described elsewhere in this book (see Chap. 27).

Figure 29-46 Metastatic myxoid liposarcoma from the groin to the breast in a 90-year-old woman. *A.* Scattered small cells against a mucoid background in Diff-Quik stain. *B.* Pap stain reveals a network of anastomosing capillaries, characteristic of the tumor.

METASTATIC TUMORS

Metastatic carcinomas and other tumors from various primary sites may occur in the breast. Several papers have described multiple sites of origin of metastases to the breast (Silverman et al, 1987; Sneige et al, 1989; DiBonito et al, 1991; Domanski, 1996; Deshpande et al, 1999).

Regardless of the site of origin, the **metastatic tumors** are always a diagnostic problem, unless they differ radically from primary tumors of the breast because of their morphology (Fig. 29-46) or contain cell products that are foreign to the breast (e.g., melanin or psammoma bodies). As a point of **differential diagnosis** with a **melanoma**, it is of interest to note that **melanocytic colonization of mammary**

P.1123

carcinoma by pigment from the skin was first reported by Azzopardi (1979) and was also observed by Gadkari et al (1997) in an aspiration smear.

Although the patient's history may include a malignant tumor in another site, **the possibility of a new primary breast cancer can never be ruled out.** Particularly difficult to diagnose are the relatively frequent metastatic **adenocarcinomas of ovarian or renal origin**, which may mimic breast cancer to perfection. The possibility of **two synchronous primary tumors** in the breast (i.e., carcinoma and primary or metastatic malignant lymphoma) should always be considered.

The diagnosis of a metastatic tumor to the breast depends to a large extent on **knowledge of the patient's clinical history** and the cytologic or histologic **patterns of the primary tumor.**

Table 29-6 lists the relatively common metastatic malignant tumors of the breast and their site of origin.

ACCURACY OF ASPIRATION BIOPSY OF PALPABLE BREAST LESIONS

Aspiration biopsy cytology aims to differentiate benign breast lesions from carcinoma. The statistics clearly document that **experience** with the method **is an important performance factor** (see Chap. 28). When the Swedish investigators Franzén and Zajicek (1968) began their work in the 1950s, they were essentially self-taught and had no grounding in histopathology. In 1,009 histologically diagnosed benign breast lesions studied at the Radiumhemmet in Stockholm between 1955 and 1964, the diagnosis was negative for cancer in 97.2% and "suspicious" in 2.8% of the patients.

In **mammary carcinoma**, the performance of this team during the same time period was much less satisfactory. In 1,068 histologically proved mammary carcinomas, 77% of the smears were reported as carcinoma, 13% were "suspicious," and almost 10% were "negative." With experience the results improved, and in 1964 the percentage of positive smears in cancer patients rose to 83%, the rates of "suspicious" smears dropped to 11%, and "negative" smears decreased to 6% of the cases (Zajicek, 1974). **Improved diagnostic accuracy was obtained when the aspiration procedure was repeated in doubtful or negative smears in clinically suspicious patients.** This was the procedure used in 1974, when, as Table 29-7 shows, more than 92% of the breast carcinomas were accurately diagnosed, only 6% were considered cytologically "suspicious," and the false-negative results dropped to about 2% of

the cases. It is evident from these statistics that **experience with the method is an essential ingredient of success**, but that even in experienced hands **negative or atypical cytologic findings do not guarantee that a lesion is benign**. The diagnosis of “**suspicious**” was particularly disconcerting because it occurred in 2.8% of benign lesions and in 6% to 13% of cancers. **It is evident that a core or surgical biopsy should be requested in all cytologically, clinically, or radiologically doubtful cases.**

Some pertinent data from the earlier literature concerning false-positive and false-negative cytologic reports in **clinically suspected** carcinoma of the breast are also presented in Table 29-8, and data on the **sensitivity and specificity of the method**, compiled by Frable (1989), are shown in Table 29-9. The Frable data, which were taken from several sources, show a **specificity** of about 96% to 97%, suggesting that the **reliability of a cytologic diagnosis of cancer is high**. However, the **sensitivity of the procedure (between 70% and 85% in the aspiration biopsies)** was much lower.

P.1125

An important study by Zarbo et al (1991) summarized the results from 294 American laboratories that participated in a survey organized by the American College of Pathology. The results, which reflect early experience with the method, were not satisfactory. Of the 13,066 cases reviewed, the **accuracy** of the method was estimated at **90%**, and the **specificity** of the test was estimated at **82%**. There were **3% false-positive**, **18% false-negative**, and **17% inadequate smears**. Giard and Hermans (1992) reviewed 29 reports from different laboratories and noted a **sensitivity that varied from 61% to 98%**, and a **specificity of 34% to 100%**. Another study pertaining to 1,018 American laboratories participating in the Interlaboratory Comparison Program of the College of American Pathologists (Young et al, 2002) recorded a false-negative rate of 6.2% and a false-positive rate of 1.1%. However, the recognition of **tumor type** was unsatisfactory, particularly for lobular, medullary, and colloid (mucinous) carcinomas.

Considering that the data cited above pertain to work performed 10 to 15 years before the time of this writing (2004), it is a legitimate question as to whether the performance of breast aspiration cytology has improved in more recent years. Arisio et al (1998) reviewed 59 reports from the literature encompassing 70,750 patients for the years 1983 to 1996, and reported an overall **sensitivity of 84% (range: 61% to 98%)** and **specificity of 97% (range: 56% to 100%)**, with less than **1% false-positive** and **6% false-negative smears**. There were considerable differences among the laboratories, which was also emphasized by Collaco et al (1999).

Experience and expertise in sampling and interpretation obviously play a major role in the performance of individual laboratories, as emphasized by Cohen et al (1987) and Ljung et al (2001). Ljung et al (2001) reported that physicians trained in the use of the aspiration technique missed 2% of breast carcinomas, whereas physicians without formal training missed 25%. Similar discrepancies were observed in referrals to surgery: lack of expertise resulted in the referral of 30% of patients with benign lesions, as compared with only 8% referred by experienced observers. The highly specialized team at the M.D. Anderson Hospital in Houston, headed by Sneige (1993), reported a **sensitivity of 96%, specificity of 99%, positive predictive value of 99%, and negative predictive value of 94%** based on 1,995 cases. Boerner and Sneige (1998), from the same institution, studied 4,455 aspirates of palpable lesions and reported **only 1.1% false-negative results**, half of which were caused by **inadequate smears**. Nearly identical results were reported by Layfield et al (1997) and Feichter et al (1997). In a study based on personal experience with 4,110 patients and the use of **cell blocks to supplement smears**, Arisio et al (1998) reported a **sensitivity of 94.6%, specificity of 99.9%, and accuracy of 98.8%**. Of these cases, 0.3% were false-positive and 1.4% were false-negative. Sanchez and Stahl (1996) noted that the most common **cause of**

false-negative smears in breast cancer is poor aim with the aspirating needle and, rarely, misinterpretation of the cytologic evidence by experienced observers. However, this is not always the case, as illustrated in a study conducted by Sidawy et al (1998). In that study, 12 smears (six fixed and stained with the Papanicolaou method, and six air-dried and stained with Diff-Quik) were assessed by six pathologists with considerable experience in mammary cytology. In only two of the cases (both with obviously malignant cells), a consensus was achieved. In the remaining cases, no agreement could be achieved with a kappa (agreement) value of 0.35, **indicating essentially no consensus** (the value of perfect agreement is 1.0).

The conclusions pertaining to the accuracy of breast aspiration cytology in palpable lesions are that the method has a very high degree of reliability when the diagnosis of breast cancer can be confidently established in aspirated material by experienced observers, but the performance of the system is much less reliable in ruling out cancer if the cytologic evidence is scanty or difficult to interpret. Thus, one must accept that FNA of palpable breast cancers carries with it a margin of false-negative error that with experience may be reduced to about 1%.

It is of interest to **compare the performance of FNA with core needle biopsies** in patients with palpable breast cancer. Ballo and Sneige (1996) reviewed 124 cases in which such a comparison was possible, and reported that the specificity of the two procedures was 100%, but the **sensitivity of FNA (97.5%) was significantly better than the sensitivity of core biopsies**, which was only 90%. The differences were statistically significant ($p < 0.004$).

ACCURACY OF STEREOTACTIC NEEDLE BIOPSY IN CLINICALLY OCCULT BREAST LESIONS

With the increasing use of mammography and ultrasonography for the detection of mammary cancer, the efficacy of the procedure must be examined from two points of view:

- How reliable is a diagnosis of mammary carcinoma that is established from a small sample of cells aspirated from a lesion barely 2 to 5 mm in diameter?
- How reliable is a diagnosis of “no cancer cells present” under these circumstances? Is it safe to follow such patients without surgical biopsy or removal?

Both questions were addressed in an early summary of experience with 2,594 nonpalpable breast lesions in Stockholm (Azavedo et al, 1989), where the stereotactic aspiration system was first introduced. **Of the 2,005 samples judged to be benign by mammography and cytology, only one patient developed carcinoma. In other words, the method had a very high negative predictive value.** Of 567 samples for which surgical removal of the lesion was recommended because of either mammographic findings or cytologic diagnoses, 451 were diagnosed as mammary carcinoma and 116 were diagnosed as benign lesions (false negative). The conclusions of that paper were that **in competent hands, the combination of mammography and stereotactic aspiration of the breast is a reliable method for the diagnosis of “no cancer present.”** However, cytology

P.1126

alone failed to identify a substantial proportion of small occult carcinomas.

Masood et al (1990) reported on 100 patients aspirated under mammographic control. Three of 20 carcinomas were missed (two were lobular carcinomas in situ, and one was ductal carcinoma in situ). The **specificity of the diagnosis of cancer was 100%**, whereas the

method had a sensitivity of 85% and accuracy of 96.7%. Fajardo et al (1990) also reported a diagnostic specificity of 100%. Kljianienko et al (1998) reported **false-negative results in 12 (about 11%) of 105 cancers** documented by biopsy with no falsepositive errors. Writing from the same institution (the Curie Institute in Paris), Cote et al (1998) reported the results of stereotactic FNA cytology in 238 patients with 243 occult breast lesions who underwent subsequent tissue biopsies. Of **107 benign lesions**, full agreement between cytology and histology was achieved in only 75 (70%) lesions. Four smears were “suspicious,” and 28 (26%) were unsatisfactory. Of **136 malignant lesions**, full agreement between cytology and histology was achieved in only 73 (54%) of carcinomas, whereas 15 smears were “suspicious,” 12 were “benign,” and 36 (26.5%) were unsatisfactory. Although no false-positive diagnoses were rendered, the large number of “suspicious” smears with either benign or malignant breast lesions shows the limitations of the technique. A very large number of unsatisfactory smears in this series (64% or 26% of the aspirates) suggest a major problem with securing adequate samples from small lesions.

Information on **ultrasound-guided aspiration biopsies** was provided by Sneige et al (1994) based on experience with 586 patients. They reported a **false-negative rate of 2%** and a **false-positive rate of 1%**, with an overall **sensitivity of 91%** and **specificity of 77%**, which are not much different from the results cited above. Similar observations were reported by Lahaye et al (1991) and Saarela et al (1996). Boerner et al (1999) reported on 1,639 patients with 1,885 FNAs obtained under ultrasound guidance. Mammary carcinoma was diagnosed in 3.7% of smears classified as “benign,” 52.9% classified as “atypical,” 75.8% classified as “suspicious,” and 98.8% classified as “malignant,” for an aggregate **sensitivity of 97.1%** and **specificity of 99.1%**.

These reports have been superseded by an elaborate study of the **efficiency of stereotactic FNA in comparison with tissue core biopsy** (Symmans et al, 2001). This comparison of results from the two methods was based on personal experience and a review of 16 published reports, with emphasis on **negative predictive value** (i.e., whether the negative diagnosis does indeed indicate a benign lesion). The **negative predictive value and the diagnosis of breast cancer** were about **2% to 10% higher for the core biopsy than for the FNA**. The results were related to cytologic sample adequacy (**nondiagnostic smears**), a factor that obviously depends on the size of the lesion and the skill and experience of the operator, as discussed above. It must be stressed that tissue core biopsies also have a false-negative rate, even in palpable lesions of the breast, as reported above (Ballo and Sneige, 1996). To a significant extent, the choice of the sampling method rests on the expertise of the medical personnel obtaining the samples. For people trained in tissue pathology, core biopsies are preferable. In institutions with a team that is competent in FNA, malignant breast lesions will be diagnosed that may be missed on core biopsies and sometimes even excisional biopsies.

Personal experience and a review of the literature strongly suggest that there are some **major differences** between aspiration cytology of **palpable lesions and small lesions sampled under mammographic or ultrasound guidance**. The **rate of false-positive cytologic diagnoses is generally lower for the small lesions**, probably because few abnormalities (such as fibroadenomas or benign mastopathy) that are the source of diagnostic difficulty (see below: atypical smears) are sampled. **On the other hand, the rate of “false-negative” smears is higher**, for two reasons:

- **The very small lesions are difficult to sample and may be missed by the needle.**
- **Some of the lesions discovered by imaging, such as lobular carcinoma in situ or**

very well differentiated ductal carcinomas in situ, are very difficult to recognize in smears.

Adequacy of Smears

Because many or most false-negative results in breast cancer apparently are caused by inadequate material, Layfield et al (1997) established the following **criteria for smear adequacy**:

- **The presence of at least six clusters of epithelial cells in all smears**
- **The presence of 10 or more myoepithelial (bipolar) cells in 10 consecutive medium-power viewing fields of the microscope (objective 20 or 25×).**

Although these criteria have been generally accepted as valid, they are **not realistic for fibrous mastopathy**, which often (even with multiple passes) does not yield any epithelial cells, or may yield less than six clusters. **Using three (or at the most four) passes does not necessarily improve the yield of the aspiration, particularly for very small lesions** (Pennes et al, 1990). The presence of myoepithelial cells is irrelevant in mammary carcinomas, wherein such cells are either absent or very few in number.

The issue of smear adequacy was also addressed by the **Consensus Conference on the Uniform Approach to Breast Fine Needle Aspiration, sponsored by the National Institutes of Health (1997)**. Instead of recommending a numerical value, the conference participants left it to the discretion of cytopathologists to decide whether the material is adequate in view of the clinical data.

Reporting of Mammary Aspiration Smears

Following a plea by Sneige et al (1994), the **National Cancer Institute Consensus Conference on Breast FNA (1997)** suggested the use of the following terminology in reporting mammary aspiration smears (as summarized below with slight modifications):

- **Benign: There is no evidence of abnormalities.**
- **Atypical/ indeterminate: The cellular findings are not diagnostic, and should be correlated with clinical and**

P.1127

mammographic data (i.e., the triple test; see the opening pages of this chapter).

- **Suspicious/probably malignant: The findings are suggestive but not unequivocally diagnostic of cancer.**
- **Malignant (or positive): There is conclusive evidence of cancer. It was suggested that the type of cancer and nuclear grade (see below) should be provided.**
- **Unsatisfactory: The reasons should be listed (e.g., scant cellularity, smearing artifacts, obscuring blood, or inflammation).**

The above nomenclature verbalizes and closely resembles Papanicolaou's classes for cervicovaginal smears (see Chap. 11) and covers all of the diagnostic possibilities in the interpretation of aspirated cytologic material. However, the nomenclature does not address the critical issues of **atypical and suspicious smears**.

“Atypical” and “Suspicious” Smears

Regardless of the degree of sophistication and excellence of the methods used to sample breast lesions, in a certain number of cases **benign epithelial cells, which occur in clusters or singly, may show nuclear enlargement and hyperchromasia** (Koss et al, 1992; Sneige, 1993; Stanley et al, 1993; Al Kaisi, 1994; Mulford and Dawson, 1994). The most common cause of diagnostic difficulties is **fibroadenomas**, but atypical cells may also occur in **duct hyperplasia, fibrous mastopathy, nipple adenomas, fat necrosis**, and other benign conditions discussed above. The interpretation of such smears must rely on the **background** of the smears: **the presence of myoepithelial (bipolar) cells** is strongly in favor of a benign lesion, at the risk of missing an occasional tubular carcinoma (see above).

If atypical cells are present, the clinical history of the patient, and mammographic and palpatory findings are helpful in reducing the number of “I don't know” diagnoses. **In all debatable cases, a tissue biopsy should be recommended. It is better to request an unnecessary biopsy than to miss a breast cancer.**

In my experience, most suspicious smears should also be reassessed in conjunction with clinical findings, and, after they are reviewed by another expert observer, they may often be reclassified as either benign or malignant. On the other hand, in the presence of marked inflammation, one should exercise extreme caution in diagnosing a malignant lesion, and such smears should be reported appropriately. The presence of excessive blood in the smears is caused by poor aspiration technique and should be so reported.

ANCILLARY STUDIES TO ASSESS THE PROGNOSIS OF BREAST CANCER IN WOMEN USING ASPIRATED CYTOLOGIC PREPARATIONS***Breast Cancer Panel***

A number of factors that may be **studied and quantitated in aspiration smears** or cell blocks of the breast appear to be of clinical and prognostic value. The make-up of a breast cancer panel is as follows:

- **Nuclear grading**
- **DNA ploidy**
- **Estrogen and progesterone receptor binding**
- **Proliferation index**
- **Expression of molecular markers (HER-2/neu)**

Undoubtedly, with time other parameters will also be measured. The techniques used in these measurements are described in Chapters 45 and 47.

The rationale behind the breast cancer panel is as follows: There is evidence that carcinomas of the breast with a diploid DNA content and a small proliferation fraction **have a better prognosis than aneuploid breast cancers with a high level of proliferating cells**. The diploid-range tumors usually have **low-grade nuclei** and **express estrogen receptors**, and thus **respond to hormonal manipulation**. Highly aggressive tumors that are aneuploid have no estrogen or progesterone receptors, have a low level of HER-2/neu protein expression, and respond to chemotherapy, even though the response may be only temporary (Coulson et al, 1986; Bacus et al, 1988, 1989, 1990; Fallenius et al, 1988; Colley et al, 1989; Kommoss et al, 1989). There is also evidence that some **tetraploid tumors** of intermediate degree of

aggressive behavior express high levels of the HER-2/neu oncogene (Ravdin and Chamnes, 1995).

Nuclear Grading

Nuclear grading is the assessment of nuclear abnormalities. It was first proposed for histologic sections of breast cancer with long-term follow-up by Bloom and Richardson (1957). This procedure has been applied to aspiration smears by a number of observers, with uncertain results (Masood, 1990; Layfield, 1992; Cajulis et al, 1994; Dabbs and Silverman, 1994; Robinson et al, 1994). Moroz et al (1997) used image analysis for this purpose. The factors considered in these assessments were:

- **The size of the nuclei, with smaller nuclei indicating a lower grade of tumor** (e.g., see Fig. 29-34A), **and larger, aneuploid nuclei indicating a higher grade of tumor** (e.g., see Fig. 29-27)
- **The similarity of nuclear sizes, with dissimilar nuclei indicating a higher grade** (e.g., see Fig. 29-32)
- **The presence of a coarse chromatin pattern, large nucleoli, and mitotic figures (particularly abnormal mitoses), which are suggestive of a higher grade** (e.g., see Fig. 29-30)

In the absence of long-term follow-up of these studies, the significance of cytologic nuclear grading is not clear (Abati and McKee, 1998).

DNA Ploidy

One of the earliest methods for assessing the prognosis of breast cancer was to measure DNA content in cancer cells, either by **image analysis in smears stained with Feulgen stain, or by flow cytometry in cell or nuclear suspensions** (Auer et al, 1980; Auer and Zetterberg, 1984; Cornelisse and van Drier-Kulker, 1985; Dawson et al, 1990).

Auer et al (1980) established the basic parameters of

P.1128

DNA ploidy patterns using Feulgen-stained aspiration smears. Four types of DNA patterns were established: **diploid, diploid-tetraploid, diploid-aneuploid, and aneuploid**. In subsequent studies by Auer and Zetterberg (1984), it was shown that nearly 80% of women with diploid and diploid-tetraploid patterns were likely to survive 10 years, whereas 90% of women with aneuploid DNA patterns died within 2 years (Fig. 29-47).

These results were generally confirmed by Falenius et al (1988) and Joensuu et al (1992). Further, Falenius et al (1984) observed that **small carcinomas detected by mammography were for the most part diploid**, and hence offered an excellent prognosis. This observation is of further interest because a **significant proportion of the small lesions are tubular carcinomas** that rarely metastasize and have low malignant potential.

Proliferation Index

The proliferation index indicates the proliferation potential of a tumor. One obtains this index by studying the frequency of mitoses in a tissue section or in smears stained with **Ki-67 or MIB1 antibody**, which indicate the presence of cells entering the mitotic cycle (Pinder et al, 1994; Lehr et al, 1999). It is generally accepted that if fewer than 10% of cancer cells stain with the antibody, the prognosis is better than if more than 20% of cells express this factor. Values

between 10% and 20% have no definite prognostic value. A very strong, statistically valid correlation between tumor proliferation and disease-free survival was demonstrated by Billgren et al (2002).

S-Phase of Tumors As an Index of Proliferation

Another approach to determine tumor proliferation is to measure DNA ploidy in tumor nuclei by **flow cytometry, and calculate from the histogram the percentage of cells in the S-phase of the cycle**. High S-phase values are usually observed in aneuploid tumors and are consistent with a high level of tumor proliferation (and a poor prognosis). Low S-phase values are usually observed in diploid and tetraploid tumors (for a summary see Koss et al, 1989 and Wersto et al, 1991). This procedure, which can be used with FNA samples, is described in detail in Chapter 47.

Keyomarsi et al (2003) studied the level of **cyclin E**, which is responsible for the transition from G1 to the S-phase of the cell cycle. Women with stage 1 disease and elevation of cyclin E protein in tumors have a much higher risk of dying of breast cancer than women whose cancers did not show this abnormality, which suggests that mechanisms of mitosis have prognostic significance.

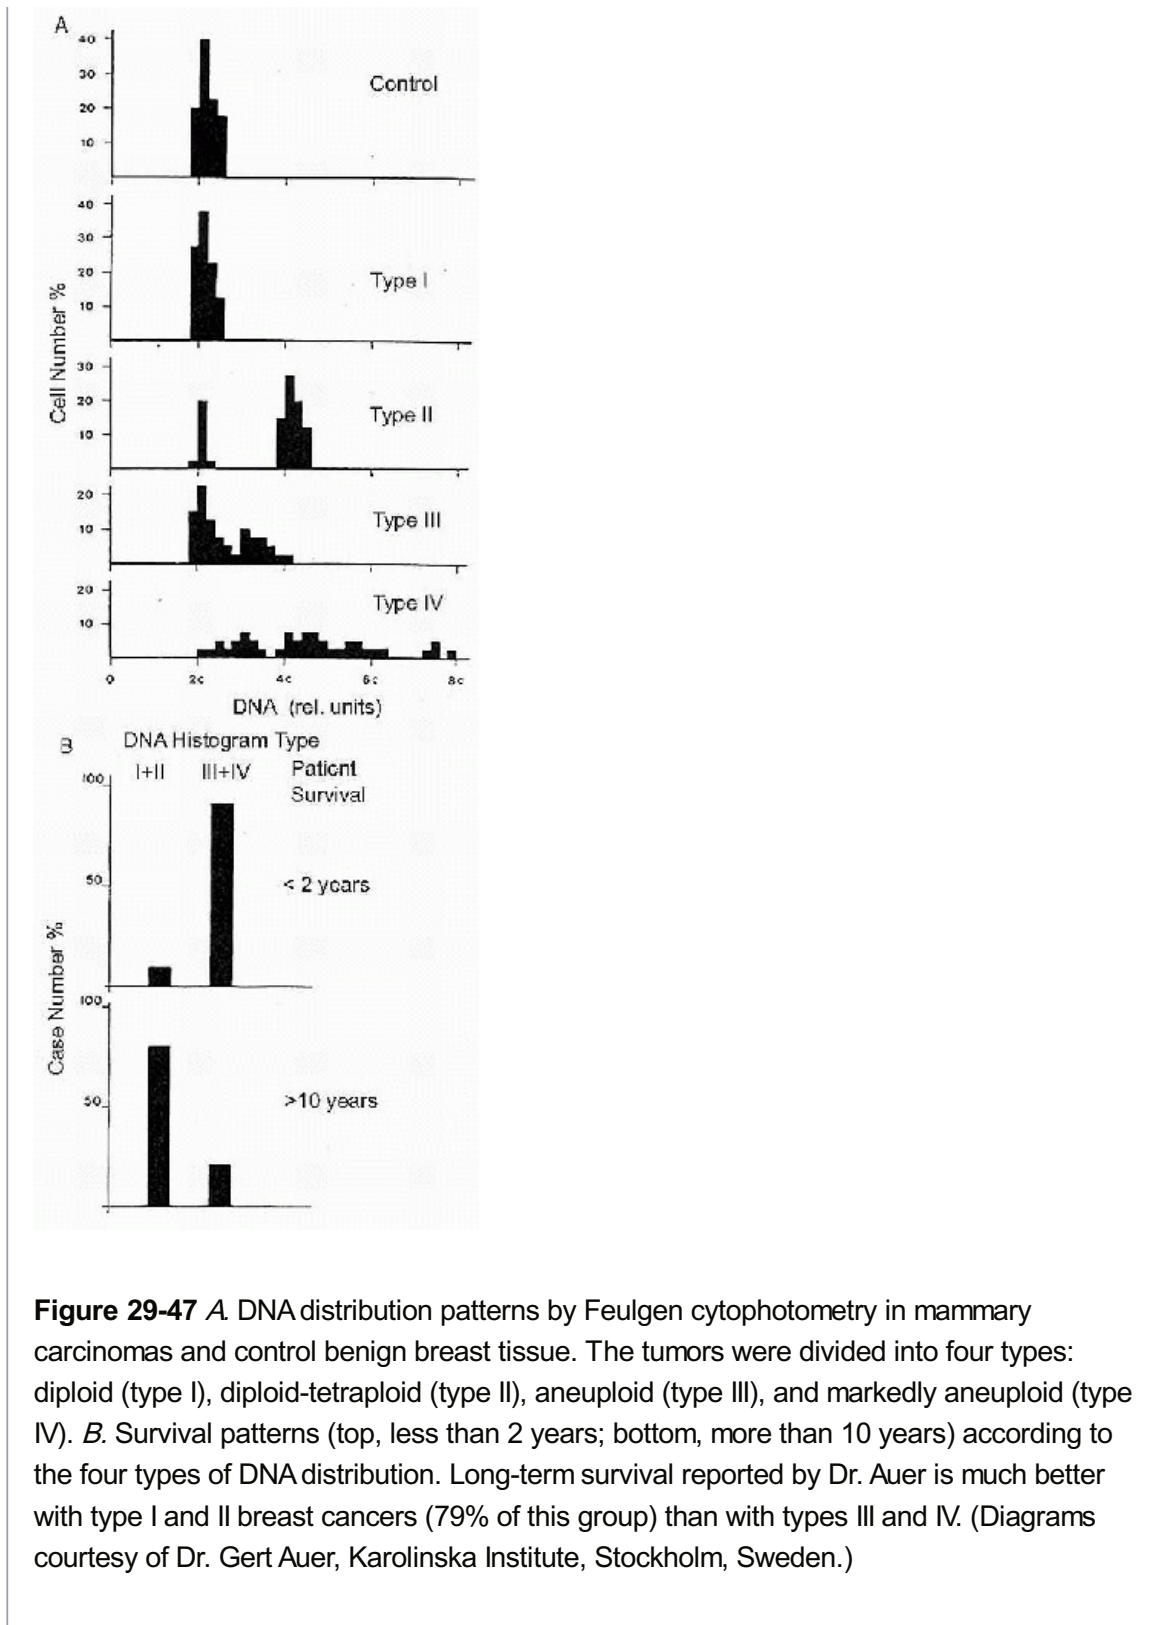

Estrogen and Progesterone Receptors

Estrogen and progesterone receptors can be easily assessed on aspiration smears with the use of the appropriate antibodies (Bacus et al, 1988; Coulson et al, 1986) (see Chap. 45). Formalin fixation of the smears is recommended.

Hormone receptors correlate with DNA ploidy. Diploid

P.1129

and diploid-tetraploid tumors are more likely to express these receptors than are aneuploid tumors (Olszewski et al, 1981). However, the presence of estrogen receptors suggests a response to hormonal therapy. In a summary paper, Masood (1992) discussed the parameters of these tests. In general, **if more than 5% of cancer cells display estrogen or progesterone receptors, the prognosis is better than if the binding occurs in less than 5%**. Riggs and Hartman (2003) suggested that **selective estrogen receptor modulators** (SERMs) may also serve as a guide to prognosis and treatment.

Molecular Markers

A number of prognostic molecular markers have been developed to assess the behavior of mammary carcinomas (Sigurdsson et al, 1990). Chief among them are the breast cancer genes, **BRCA 1 and 2**, which may be **mutated** in some families and which **predispose women to breast, ovarian, and tubal cancer** (see also Chap. 16). It has been suggested that patients with **mutations of BRCA1 tend to develop high-grade breast cancers and medullary carcinomas with lymphoid stroma**, whereas **patients with the BRCA2 mutation develop**

more heterogeneous carcinomas (Hedenfalk and Lakhani et al, 2001). These genes can be analyzed by polymerase chain reaction (PCR) on DNA extracted from lymphocytes. Some patients with these mutations may opt for prophylactic mastectomy.

Other gene abnormalities may be studied in aspiration smears by means of monoclonal antibodies. Thus, the absence or reduction of expression in the **adhesion molecules E-cadherin** may be related to the formation of metastases (Oka et al, 1993; Birchmeier et al, 1994). The expression and mutation of the **oncogene HER-2/neu** may also be determined and measured in FNA smears by immunocytochemistry and fluorescence in situ hybridization (FISH), with results comparable to those obtained in tissue sections (Corkill and Katz, 1994; Ravdin and Chamnes et al, 1995; Klijanienko et al, 1999; Couturier et al, 2000; Hoang et al, 2000; Lehr et al, 2001; Bozzetti et al, 2003). A new method for visualizing the hybridization process, using grains of gold as a marker, was described by Tubbs et al (2002). This issue has acquired practical significance because of the recent introduction of a specific drug (Herceptin) that prolongs the lives of patients who test positive for the mutation of this gene.

As discussed in Chapter 6, the **bcl-2 gene** encodes for proteins that are involved in regulating cell death or apoptosis. The **absence or mutation** of this gene prevents apoptosis and thus enhances the survival of cancer cells. Siziopikou et al (1996) observed that **the bcl-2 gene is present in all benign lesions of the breast and some well differentiated in situ duct carcinomas, but is absent in invasive cancer**. Opposite results were observed with **p53 protein products**, which is absent in benign and well differentiated malignant lesions, but is expressed in poorly differentiated in situ duct carcinomas and in invasive cancer.

These parameters can also be studied in FNA smears. Troncone et al (1995) applied immunocytologic techniques to the study of **bcl-2 gene** expression in cancer cells in smears of 54 patients and compared the results with corresponding surgical specimens from 20 of these patients, with concordant results. Bozzetti et al (1999) correlated the expression of the **bcl-2 gene** with several other parameters in FNA smears of 130 patients with mammary carcinoma. **The presence of the bcl-2 gene** in 76% of mammary carcinomas **correlated** in a statistically significant fashion with other **favorable prognostic factors**, such as the presence of estrogen and progesterone receptors, a low proliferation index, and the absence of the p53 mutation. Pollett et al (2000) correlated mutations of the **cancer gene p53** in aspirated samples compared with histologic sections, with comparable results. The clinical significance of these observations has not been established.

FISH was used by Leuschner et al (1996) to document **numerical abnormalities of chromosomes 1 and 9** in breast cancer. Again, the clinical significance of these observations is unknown, but they show the potential of this technique for further studies.

The newest development in molecular biology is **microarray assays**, which allow tumor RNA to be matched with the DNA of a large number of genes. This technique was used by Hedenfalk et al (2001) to document that gene expression profiles differed among small groups of women with BRCA1 and BRCA2 mutations and sporadic breast cancers. Similar findings were reported by Assersohn et al (2002).

Smear Pattern

Several observers have attempted to correlate the behavior of mammary cancer (notably its ability to form metastases) with the smear pattern. Dissociated smear patterns in which the cancer cells formed very few or no clusters were compared with smear patterns with a dominance of cell clusters or a combination of these patterns (Layfield et al, 1992; Yu et al,

1998; Schiller et al, 2001). Neither Yu et al (1998) nor Schiller et al (2001) found any **correlation between the smear pattern (dispersion of cells) and axillary lymph node metastases**. Layfield et al (1992) were less certain and suggested that the smear pattern does have prognostic significance, with patients showing the **dispersed pattern faring less well than patients with cancer cells that form clusters**. Long-term follow-up studies are needed to elucidate the significance of these observations. **A similar controversy exists in reference to patterns of metastatic mammary carcinoma in effusions** (see Chap. 26).

Sex Chromatin As a Prognostic Factor in Mammary Carcinoma

It has been repeatedly observed that **the presence of sex chromatin in breast cancer cells has a favorable prognostic significance** (Wacker and Miles, 1966; Kallenberger et al, 1967). In a study of 100 consecutive breast cancer patients treated by radical mastectomy, sex chromatin was evaluated on smears obtained by scraping the cut surface of the tumor (Savino and Koss, 1971) (Fig. 29-48). The presence of **20% or more cancer cells with identifiable sex chromatin resulted in much more favorable**

P.1130

tumor behavior in terms of recurrence. This observation was **unrelated to tumor grade or stage** at the time of the original surgery (see Tables 29-10, 29-11 and 29-12 for a summary). Rosen et al (1977) found a **correlation between the role of sex chromatin bodies and estrogen receptors**. This simple method for assessing breast cancer prognosis is probably as accurate as other quantitative methods of DNA measurement or estrogen receptor analysis, discussed above.

Figure 29-48 Sex chromatin (Barr body) in mammary cancer. Touch preparation of a tumor (Guard stain). A sex chromatin body is readily visible as a small, dense triangular area of heterochromatin on the inner aspect of the nuclear membrane. (Oil immersion.)

OTHER APPLICATIONS OF CYTOLOGY OF PROGNOSTIC VALUE

Sentinel Lymph Nodes

As discussed in the opening pages of this chapter, the evaluation of sentinel lymph nodes offers an important guideline for the treatment of breast cancer. The presence of metastatic cancer is of value in assessing treatment options.

Cytologic touch preparations of cross sections of sentinel lymph nodes were studied by Viale et al (1999) and Llatjos et al (2002). Sauer et al (2003) used **imprints** of lymph nodes as a rapid and reliable method for assessing metastatic tumor in most cases. The success of the method depended on the size and extent of the metastases: it was efficient and reliable in larger lesions, but was of questionable value if the metastatic deposits were very small, particularly if immunochemistry of keratins was needed to elicit their presence.

Cancer Cells in Circulating Blood and Bone Marrow

As discussed in Chapter 43, new methods for identifying cancer cells in blood and bone marrow—particularly reverse transcriptase PCR (**RT-PCR**)—have been applied to patients with breast cancer. Although the results are still controversial, they suggest that patients with evidence of cancer cells in either the blood or the marrow are more likely to have a relapse of the disease. For a detailed review of the data, see Chapter 43.

MALE BREAST

Gynecomastia is the only specific benign disorder of the male breast that may be the target of aspiration biopsy. Other disorders (notably **duct carcinomas**) occur in men, but at a much lower rate than in women. The male breast has no lactiferous apparatus; therefore, **lobular cancers do not occur in the male**.

Gynecomastia

Gynecomastia is a **swelling of one or both breasts**. It is common and transient in adolescents, and rarely requires a morphologic diagnosis or treatment. It may be more significant in adult men, in whom it may be an expression of testosterone deficiency or estrogen surplus. The latter is also observed in cirrhosis of the liver, probably as a consequence of faulty metabolism of estrogens. Bhat (1990) reported on gynecomastia in morticians, possibly as a consequence of exposure to the estrogens in cadavers.

Histology and Cytology

Gynecomastia is characterized by **proliferation of breast ducts** in a loose connective tissue stroma. The ducts are often branching and are lined by one or two layers of cuboidal cells, which sometimes form small papillary projections (Fig. 29-49C).

Aspiration biopsy of gynecomastia is performed only if there is a **suspicion of carcinoma**. Aspirates of gynecomastia are **similar to findings in fibroadenoma**, inasmuch as the dominant features are **sheets of cuboidal ductal cells and fragments of loose connective tissue stroma** (Fig. 29-49A,B). Bipolar, spindly myoepithelial cells and oncocytes are sometimes present. Apocrine cell changes have been reported and were attributed to the effect of anabolic steroids (Fowler et al, 1996). The lesion rarely causes any diagnostic problems, **except in patients undergoing chemotherapy**. In a smear from a young male patient being treated for a malignant lymphoma, we observed significant abnormalities

P.1131

of the epithelial lining cells, with large, hyperchromatic nuclei, **mimicking cancer cells to perfection** (Koss et al, 1992). In the biopsy of the breast, the ducts were lined by large, protruding cells with prominent nuclei, which were interpreted as the effects of drugs (Fig. 29-50). A somewhat similar case was reported by Pinedo et al (1991).

carcinoma of the breast. A preliminary report. *Acta Cytol* 15:373-374, 1971.)

Carcinoma

All types of **duct cancer** may occur in the male breast and can be diagnosed either by aspiration cytology or, rarely, in nipple secretions. In fact, it is easier to perform an **aspiration of the male breast compared to the female breast** because, in nearly all cases, the tumor is superficial and palpable. The cytologic presentation is identical to that of female breast cancer, as described above (Fig. 29-51). Several **variants of breast cancer** have been reported in males (Bhagat and Kline, 1990; Das et al, 1995). The question of whether male breast cancer is more common in patients with **Klinefelter's syndrome** was investigated by Nadel and Koss (1967), with negative results. However, more recent epidemiologic studies suggested that Klinefelter's syndrome is a risk factor for breast cancer (Hultborn et al, 1997; Swerdlow et al, 2001).

Nipple secretions may occur in a male patient, and may occasionally lead to a diagnosis of a duct carcinoma (Fudji et al, 1986) or ductal carcinoma in situ (Hirschman et al, 1995; López-Rios et al, 1998; Simmons, 2002).

Uncommon Tumors

Table 29-13 lists some of the uncommon tumors observed in male patients. The cytologic presentation of these tumors is identical with that of the female breast, as described above.

Accuracy of Diagnosis in Males

Four major surveys of aspiration cytology of the male breast have been conducted. Das et al (1995) described their experience with 188 aspirates, including six cancers. Lilleng et al (1995) discussed and analyzed 241 aspirates, including 24 invasive carcinomas and one carcinoma in situ. Siddiqui et al (2002) studied 614 aspirates from three major institutions, of which 427 were benign and 32 were malignant. Sixty-one smears were "atypical"/"suspicious," and 94 were inadequate. The test was calculated to have a sensitivity of 95.3%, specificity of 100%, and

diagnostic accuracy of 98%. Two features of this survey were unusual: over one half of the documented cancer cases (17 of 32) were **metastatic** to the breast, with lung cancer and melanomas most commonly observed. Nearly 15% of the aspirates were inadequate. The results were very similar to those reported by Joshi et al (1999). By far most of the benign lesions were

P.1132

gynecomastias, which were usually recognized without any difficulty. Other benign lesions occasionally encountered were **fat necrosis**, **papillomas**, and **rare soft-tissue tumors**, such as **lipomas**. In general, the male breast causes far fewer diagnostic problems than the female breast.

Figure 29-49 Gynecomastia in a 77-year-old man. *A.* At low magnification, this smear is strikingly similar to cytologic findings in fibroadenoma (see Fig. 29-18). Numerous large clusters of ductal cells and bits of stroma in the background are characteristic of gynecomastia. *B.* The clusters are composed of tightly packed cuboidal ductal cells, with a few small myoepithelial cells attached to the periphery. *C.* Histology of the lesion. The breast ducts are surrounded by loose stroma.

NIPPLE SECRETIONS

Nipple secretions should not occur in a **normal, nonpregnant, nonlactating woman**. Therefore, **nipple secretions that occur in the absence of pregnancy or lactation are, per se, abnormal**. Nipple secretions have various appearances: they can be **milky, watery** (usually reflecting milk precursor or colostrum), **serous (yellow or clear)**, **purulent (thick, yellow)**, **blood-tinged**, or **frankly bloody**. Based on a very large experience with 602 samples, Das et al (2001) observed that bloody nipple secretions are most likely to show significant abnormalities of the duct system. Such secretions are of particular interest in cancer (see below).

Figure 29-50 Atypical gynecomastia in a young patient undergoing chemotherapy for lymphoma. *A.* Thick cluster of superimposed epithelial cells with large, hyperchromatic nuclei. *B.* Histology of a breast lesion showing marked nuclear abnormalities in the ductal epithelium.

P.1133

Figure 29-51 Ductal carcinoma in situ in a 54-year-old man. *A.* Numerous irregular clusters of cancer cells against a clean background. *B.* At high magnification, the loosely structured cluster is composed of large but uniform cancer cells with relatively smooth hyperchromatic nuclei. The nucleoli are barely visible in some cells, consistent with a low nuclear grade. *C.* Tissue section from the same case showing a low-grade carcinoma in two adjacent ducts.

There are several possible reasons for such secretions. They may be caused by a **temporary hormonal imbalance** that stimulates secretion of the acini, or **benign disorders such as duct stasis or papilloma**. However, nipple secretions that resemble milk, colostrum, or serous secretions (**galactorrhea**) may occasionally occur in a variety of **endocrine disorders** that affect the secretion of prolactin or prolactin inhibitors. The most significant of these disorders are **pituitary tumors** and other diseases of the hypothalamic-pituitary axis. These disorders

must always be considered in the differential diagnosis of nipple discharge in otherwise asymptomatic women (see Chap. 9). Nipple discharge may also occur in infants with **abnormal premature breast development (telarche)**. Mangano et al (1998) reported that the nipple fluid in a 10-month-old girl contained a large number of clusters of minimally atypical hyperplastic ductal cells.

TABLE 29-13 UNUSUAL VARIANTS OF CARCINOMA AND OTHER RARE TUMORS REPORTED IN MALE PATIENTS

Type of tumor	Authors
Benign	
Graular cell tumor	Chachlani et al, 1977
Malignant	
Carcinoma with argyrophilic cells or with endocrine differentiation	Skoog, 1987; Feczko et al, 1995
Papillary carcinoma	Mockli et al, 1993
Secretory carcinoma	Pohar-Marinsek and Golouh, 1994; Vesoulis and Kashkari, 1998
Hemangiopericytoma	Jimenez-Ayala et al, 1991

Most importantly, nipple secretions may also occur in the presence of an otherwise **occult and asymptomatic cancer of ducts of the breast**. The chief value of cytologic examination of nipple secretions lies in the diagnosis of

P.1134

such cancers. The procedure should be confined to those patients who have no palpable masses in the breast or other evidence of breast cancer. If there is a clinical or mammographic suspicion of cancer of the breast, other methods of diagnosis (as discussed in the opening pages of this chapter) should be applied.

Techniques of Cytologic Examination

The original approach to the cytologic examination of nipple secretions was **a simple touch preparation** in which a clean glass slide is applied to the nipple and a smear of the fluid is fixed and processed with Papanicolaou stain. Papanicolaou et al (1958) attempted to improve the yield of cytology by using a **breast pump**. Masukawa et al (1975) enhanced the yield by breast massage and the use of multiple frosted slides. Currently, various additional modes of investigation, including radiologic imaging of breast ducts (**galactography**) and **ductal lavage**, are available to further investigate the reasons for nipple discharge. The techniques and results of these investigative approaches are discussed below.

Cytology of Nipple Secretions in the Absence of Cancer

Normal Breast

Mitchell et al (2001) studied the cellular components of artificially obtained nipple secretions in **normal women** during the menstrual cycle. The smears contained scanty benign ductal cells, regardless of the stage of the cycle.

Duct Dilatation and Stasis

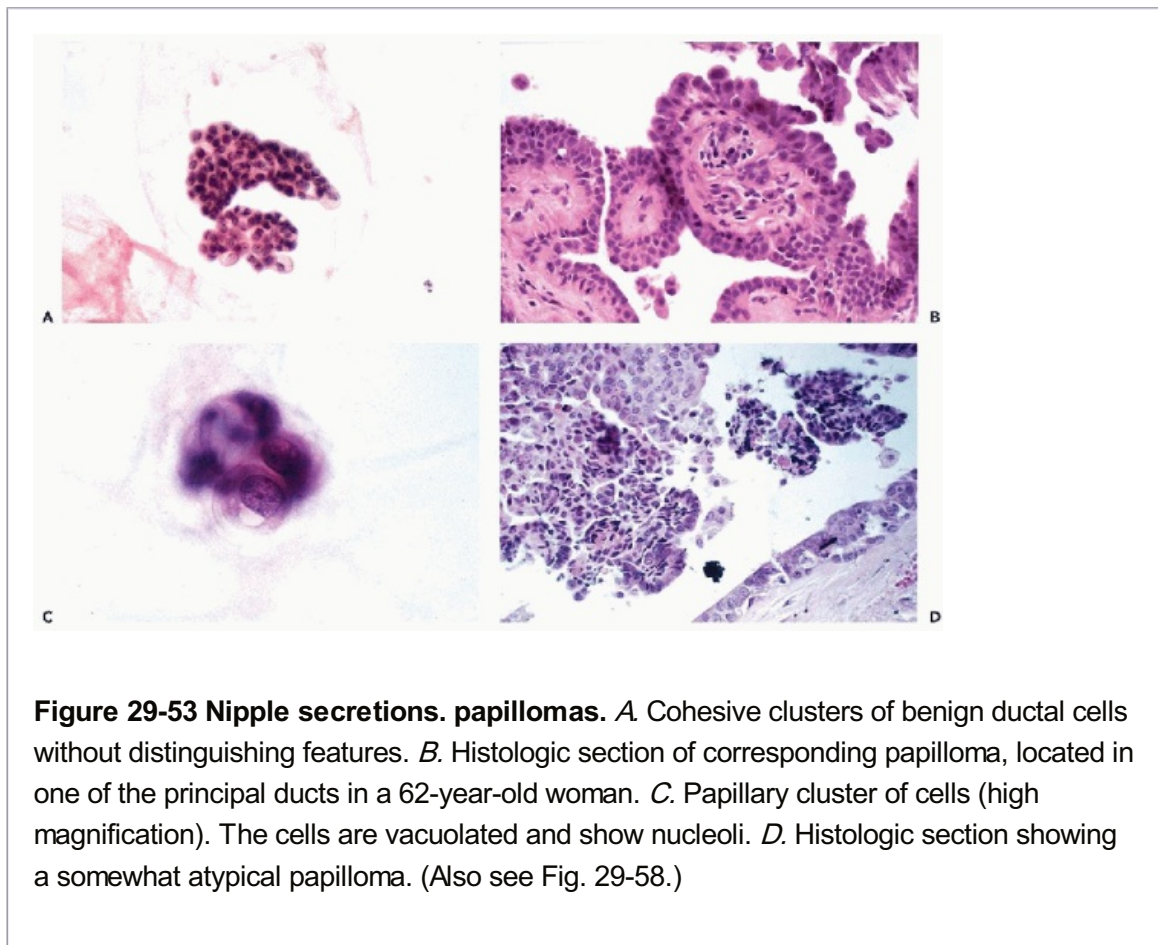

Blockage of breast ducts occurs in **inflammatory processes** or in **fibrocystic disease**, sometimes resulting in an accumulation of sticky, greenish material within dilated ducts. Such material may escape from the nipple. Cytologically, the predominant component is the **foam cell**, a fairly large, markedly vacuolated macrophage, some of which may represent a **modified duct lining cell**, as previously discussed (see Fig. 29-13). The nuclei of the foam cells may contain prominent **nucleoli**. The secretions may also contain **duct lining cells (singly or in compact linear streaks, spherical clusters, or flat sheets)**. These cells are small, often oval or columnar when single, but sometimes somewhat irregular within the papillary clusters (Fig. 29-52). Cytoplasmic vacuoles are readily observed. The nuclei are similar to those of normal ductal cells. **Apocrine metaplasia of duct lining is sometimes present.** These cells retain all the features of apocrine cells in direct aspirates (see Fig. 29-3). In patients with inflammatory events, the nipple fluid may show a varying proportion of **leukocytes** and often varying amounts of **proteinaceous material**. In the presence of **necrotic material**, which is sometimes seen in duct stasis, the presence of a ductal carcinoma should be ruled out (see below).

Intraductal Papilloma

Intraductal papilloma is a common disease of the duct system of the breast that may bring about nipple secretions, especially if the lesion is located within the main excretory ducts. In nipple secretions, **cohesive fairly large clusters of otherwise normal duct cells, sometimes with vacuolated cytoplasm** may be observed (Fig. 29-53A,B). Clusters of apocrine cells may sometimes occur. In some patients, however, papillary, **spherical clusters of large duct cells with cytoplasmic vacuoles, enlarged nuclei and visible nucleoli** may be present, usually reflecting the presence of a papilloma with atypia (Fig. 29-53C,D). Regardless of the degree of nuclear atypia in cell clusters, the **diagnosis of breast cancer should be made with extreme caution in the absence of single cancer cells**. The prognosis for most papillary lesions is very favorable, despite cellular abnormalities. Histologic examination of tissues is **advisable in all cases**. It must be pointed out that the association of **nipple adenomas with breast cancer** has been repeatedly observed (Bhagavan et al, 1973). A cytologic presentation of papillomas in ductal lavage specimens is shown in Figure 29-58.

Other Rare Benign Findings

Lahiri (1975) observed **microfilariae** in nipple secretions. Masukawa (1972) observed calcific concretions and **fungal organisms** in filamentous and yeast forms. A case of **tuberculosis of the breast** with nipple secretions is illustrated in Figure 29-9C.

Nipple Secretions in Breast Cancer

It has been determined in several large studies that **bloody nipple secretions** are more likely to contain cancer cells compared to other types of secretions. **Still, other types of secretions cannot be ignored** even though there is a lower probability of a cancer diagnosis. Ciatto et al

(1986), who studied nipple secretions in 3,867 women, observed that the prevalence of cancer was 3.96% in patients with bloody nipple discharge, 0.83% in patients with purulent discharge, 0.16% in patients with serous discharge, and 0.13% in patients with a milky discharge. Takeda et al (1990) reported on cytologic analyses of nipple discharge in 20,537 women. Of 61 women with breast cancer, 25 had nipple secretions that were either positive or suspicious for cancer, and in 10 of these patients this was the first evidence of disease. Less than one half of the nipple secretions were bloody. Similar observations have been reported by Leveque and Priou (1990), Johnson and Kini (1991), Das et al (2001), and Dinkel et al (2001).

Two subtypes of cancer of the breast may be manifested in spontaneous nipple secretions: **solid or papillary ductal carcinoma**, which may be in situ or invasive, and **duct carcinoma associated with Paget's disease of the nipple**. Tumors that yield cells of diagnostic value are usually located within the main ducts of the breast.

P.1136

Figure 29-54 Ductal carcinoma in situ (comedo type) in nipple secretions. A-C. Poorly preserved cancer cells with large pyknotic nuclei in a background of debris and scattered inflammatory cells. **D.** Corresponding tissue section showing duct carcinoma with necrosis (see also Fig. 29-59).

Figure 29-55 Two more examples of breast cancer in nipple secretions. *A.* Papillary cluster of large cancer cells. *B.* Corresponding tissue section showing ductal carcinoma in situ. *C.* Large cluster of cancer cells corresponding to invasive carcinoma shown in *D.*

P.1137

Duct Carcinoma

In nipple secretions, the cancer cells desquamate **singly or in clusters** (Figs. 29-54 and 29-55). **The clusters may be loosely structured, and are sometimes thick or spherical, but may show a relatively orderly arrangement of cancer cells in papillary clusters** (Fig. 29-55A). The features of cancer cells in nipple secretions are the same as in direct aspirates, except that **necrosis is quite common in high-grade lesions, particularly in ductal carcinoma (in situ comedo type)**, and may result in **poorly preserved cancer cells with large, dark nuclei and frayed cytoplasm** (see Fig. 29-54).

A diagnosis of cancer of the breast in nipple secretions should be made only on the basis of irrefutable evidence, and preferably in the presence of single cancer cells. If the evidence is questionable, other methods of investigation must be suggested before therapy is instituted.

Figure 29-56 Atypical hyperplasia of ducts in nipple secretions. A-C. High magnification to show dense clusters of markedly atypical ductal cells with enlarged, hyperchromatic nuclei. There were no single abnormal cells in the smear. D. Representative histologic field of breast biopsy showing a markedly atypical configuration of epithelium. It may be argued whether this is an atypical hyperplasia or ductal carcinoma in situ.

Atypical Hyperplasia of Ducts

On rare occasions, nipple secretions may contain **compact clusters of highly abnormal ductal cells with large hyperchromatic nuclei** that do not correspond to classic duct carcinoma on histologic review of ample biopsy material. A case in point is that of a 38-year-old patient with bloody nipple discharge (shown in Figure 29-56). The histologic lesion in this case was an **atypical hyperplasia of ducts**, presumably a precancerous lesion; however, to my knowledge, this patient did not develop breast cancer during several years of follow-up. A similar case, diagnosed in ductal lavage, is illustrated in Figure 29-59. For further comments on atypical ductal hyperplasia, see above.

Paget's Disease of the Nipple

Clinical Presentation and Histology

In this form of cancer of the breast, there is involvement of the nipple, which appears red on inspection and **clinically may suggest an allergic reaction or an inflammatory lesion**. Paget's disease is usually **unilateral, whereas the benign skin disorders usually affect both breasts**. Histologically, **the epidermis of the nipple is permeated with large, clear cancer cells (Paget's cells)** (Fig. 29-57B). In most cases, there is an **underlying duct carcinoma that is**

P.1138

often remote from the nipple. We have also observed a case of Paget's disease in which the underlying lesion was a lobular carcinoma in situ (not shown). Whether Paget's disease is an epithelial disorder caused by the underlying cancer, or an actual repository of cancer cells

traveling to the epidermis of the nipple via periductal lymphatics, as suggested by Toker (1967), remains an unresolved mystery. The prognosis of Paget's disease of the nipple depends entirely on the type and stage of the underlying breast cancer (Ashikari et al, 1970).

Cytology

Touch preparations or scrapes of the nipple lesion may disclose the presence of large Paget's cells in the company of epidermal cells or sometimes conventional cancer cells (Fig. 29-57A). Some cases of Paget's disease of the breast may be accompanied by **nipple secretions, which** may show **duct cancer cells** (Fig. 29-57C,D). We have not observed Paget's cells in nipple secretions. Kobayashi et al (1997) reported a case of **pemphigus vulgaris** of the nipple masquerading as Paget's disease.

Detection of Occult Breast Cancer in Nipple Secretions and Ductography

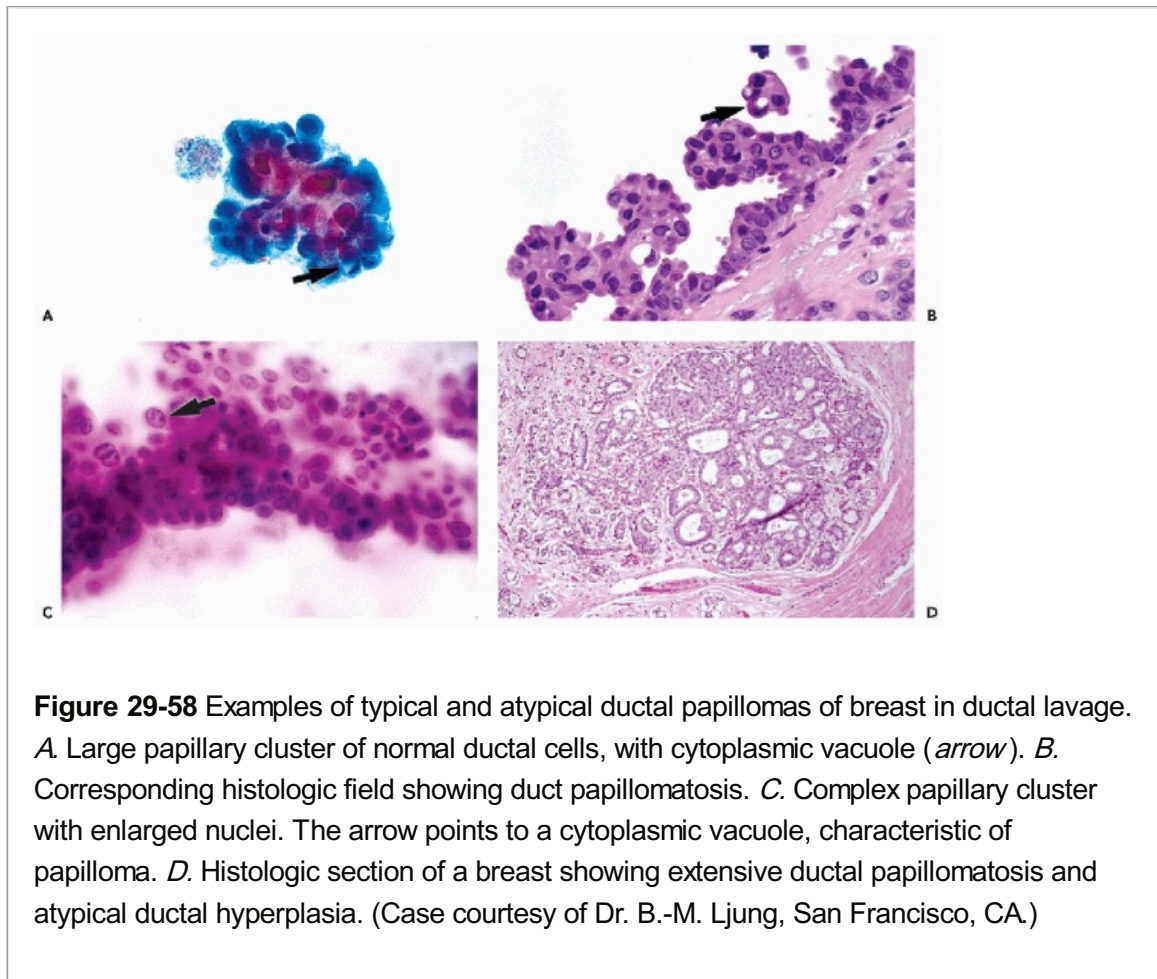

Unfortunately, nipple secretions, whether spontaneous or obtained by a special breast pump, are **not a very efficient means of detecting occult carcinoma of the breast**. Papanicolaou et al (1958) attempted to diagnose occult breast cancer by cytologic examination of nipple secretions obtained by **breast pump**. Only one case of breast cancer was identified in 917 asymptomatic patients. Better results were reported by Masukawa (1975), who advocated the use of direct **nipple touch preparations** with multiple frosted slides. Sartorius (1977) devised a **nipple aspiration apparatus** that obtained breast fluid by means of a double vacuum system. He reported that a sufficient amount of nipple fluid for cytologic examination was obtained in approximately 55% of all women examined, but in only 30% of women younger than 20 and older than 60 years of age. In a group of women classified as a "high-risk group" because of a family history of breast cancer, the rate of "atypical" cells was higher than in

normal women. **Malignant cells were observed in 49 patients with documented breast cancer, including seven with lesions smaller than 0.8 cm in diameter, with no clinical or mammographic evidence of disease.** In these patients, the disease was localized by injection of contrast medium into the ducts (**contrast ductography**). It appears that the nipple aspiration method devised by Sartorius can contribute to the detection of early breast cancer. Similar conclusions were reached by Wunderlich (1977).

Ductography was applied on a fairly large scale for the follow-up of women with nipple discharge and no evidence

P.1139

of abnormalities by Cardenosa and Eklund (1991) and Dinkel et al (2001), with interesting results. In Dinkel et al's study, only 10 of 153 patients (6.3%) with duct abnormalities were shown to harbor carcinomas. Currently under development is **fiberoptic ductoscopy**, which allows a direct visualization of the intraductal lesions, and which, according to Shen and Dietz (2001), is the most accurate method for diagnosing intraductal lesions. Cytology of nipple secretions cannot be considered a replacement for other methods of breast cancer detection, such as mammography or ultrasound, but it occasionally may contribute to early diagnosis.

DUCTAL LAVAGE

Contributed by Dr. Britt-Marie Ljung

The development of a novel **two-way microcatheter** makes it possible to lavage individual breast ducts through their openings in the nipple. Ductal lavage is currently limited to women at **high risk of breast cancer** because of a history of the disease in the opposite breast, breast

cancer in close female relatives, or mutations of BRCA genes I and II (Dooley et al, 2001; O'Shaughnessy et al, 2002; personal communication from Dr. B.-M. Ljung). The procedure is performed under local anesthesia and is **limited to women who produce nipple fluid after breast massage** with a suction cup. The duct to be investigated is identified by a droplet of residual fluid on the surface of the nipple. A catheter is introduced into this duct for a distance of about 1.5 cm. A small amount of additional anesthetic is then injected, followed by a small amount of saline that is instilled and reaspirated. The collected fluid specimens have many features in common with nipple aspirates (Sartorius, 1977) (see above), but are much richer in cells, averaging about 13,500 per specimen (Dooley et al, 2001). The specimens are classified according to the guidelines of the National Cancer Institute Consensus Conference (1997) for aspiration biopsies (see above).

In women whose duct fluid shows cancer cells, the lesion is localized and treated. Other patients are followed on the assumption that women with atypical epithelial cells, in either nipple aspirate or duct lavage fluid, are at high risk for developing mammary carcinoma in the future (Wrensch et al, 1992, 1993).

Cytology

Normal benign specimens typically show **epithelial cells**, singly and in well organized clusters. The single columnar

P.1140

duct cells have a well-preserved cytoplasm. The nuclei in single cells are small and oval, and have condensed chromatin. Clusters of normal epithelial cells are organized in "honeycomb" layers surrounded by myoepithelial cells. The nuclei of the epithelial cells are open, with evenly dispersed chromatin and small single nucleoli; however, very small, condensed nuclei may also be seen (see Fig. 29-2C). The **myoepithelial cells** have small, condensed oval nuclei (see Fig. 29-5). It is not unusual to see rather complex three-dimensional clusters consistent with the architecture of a **lobular unit** (see Fig. 29-4A). The appearance of normal breast epithelium in clusters is very similar to that seen in FNA specimens. Nonepithelial cells account for an average of 50% of the cells in ductal lavage specimens. Most of these cells are foam cells, other macrophages, and lymphocytes.

Figure 29-59 An example of mammary ductal carcinoma in situ in ductal lavage. *A.* Poorly preserved cancer cells (*arrow*) in the background of necrosis. *B.* A better-preserved cluster of cancer cells (*arrow*). *C,D.* Lower- and higher-magnification views of the corresponding breast tissue showing a high-grade DCIS. (Case courtesy of Dr. B.-M. Ljung, San Francisco, CA.)

Papillomas show characteristic features, including cell clusters with papillary architecture, moderately enlarged nuclei of variable sizes, mild to marked hyperchromasia, and sometimes irregular nuclear membranes. Abundant, dense, well defined cytoplasm is typical, and the cytoplasm frequently features large, prominent vacuoles (Fig. 29-58A,B).

The lavage specimens may show varying degrees of **atypia**, in a manner similar to reported findings on nipple aspirates associated with an increased risk of developing breast cancer (Wrensch et al, 1992, 1993). The atypical cells show **varying degrees of nuclear enlargement, hyperchromasia, and irregular nuclear membranes. Enlarged and multiple nucleoli, as well as an increased nucleocytoplasmic ratio, may also be seen. Architectural abnormalities, including multilayered, crowded clustering; lack of myoepithelial cells; and papillary formations are also signs of abnormal epithelial cells.** Breast biopsies in such cases may disclose **atypical ductal hyperplasia** (see Fig. 29-58C,D).

Carcinomas

In a small subset of cases, **frankly malignant cells are identified.** These cells have features in common with breast cancer in other settings, including hyperchromasia, significant nuclear size variability and overall enlargement, variable or high nucleocytoplasmic ratios, and irregular multilayered architecture. Myoepithelial cells are absent in the case of high-grade DCIS (Fig. 29-59), and there is usually evidence of necrosis in the form of nuclear debris.

The full clinical significance of ongoing studies of ductal lavage as a technique that may contribute to early breast cancer diagnosis, and thus salvage lives, may not be evident for several years (O'Shaughnessy et al, 2002).

It was recently suggested that nipple aspirate fluid can be used for **proteomic analysis**, which can differentiate between normal breast and cancer (Paweletz et al, 2001). Cells from this fluid are suitable for **immunocytochemistry** (King et al, 2002) and **molecular analysis** by PCR (Evron et al, 2001).

P.1141

ACKNOWLEDGMENT

I thank Dr. Britt-Marie Ljung, Professor of Pathology at the University of California-San Francisco, for her critical review of this chapter.

The Thyroid, Parathyroid, and Neck Masses Other Than Lymph Nodes

Miguel A. Sanchez

Rosalyn E. Stahl

THE THYROID

Biopsy Principles and Techniques

The primary objective of fine-needle aspiration biopsies (FNAs) of the thyroid **is to select those patients who require surgery for a neoplastic disorder from those who have a functional or inflammatory abnormality and who can be followed clinically or treated medically** (Poller et al, 2000; Werga et al, 2000; Carpi et al, 1996, 1999; Mazzaferri, 1993; Cohen and Choi, 1988; Einhorn and Franzén, 1962; Söderström, 1952). Children and adolescents should not be excluded because they may also harbor malignant tumors (recent summary in Khurana et al, 1999).

The clinical evaluation of a thyroid mass includes radioiodine scanning (scintiscan), ultrasound and biochemical or immunologic thyroid function tests. However, for palpable lesions of the thyroid, this initial work-up is often of limited value. Although most thyroid tumors are "cold" on scintiscan (i.e., do not absorb radiiodine), some are not, but not all "hot nodules" represent functional abnormalities. Eighty per cent of ultrasounds describe the thyroid masses as "partially solid and partially cystic," which does not contribute to the diagnosis. Thyroid function tests are usually

P.1149

normal in tumors. Therefore, our approach **in evaluating a palpable thyroid mass is to begin with fine-needle aspiration biopsy**, which we found to be a safe procedure as have many others (Castro and Gharib, 2000; Werga et al, 2000; Mazzaferri, 1993; Gagneten et al, 1987; Rojeski and Gharib, 1985; Löwhagen and Willems, 1981; Wang et al, 1976; Löwhagen and Sprenger, 1974). Using this approach, we have performed approximately 10,000 fine-needle aspiration biopsies of the thyroid, most guided by palpation and the others under ultrasound guidance.

The use of scintiscanning and ultrasound is not to be dismissed, however, because in individual patients, these tests may complement FNA (Baloch et al, 2000; Tambouret et al, 1999; Capri et al, 1996, 1999; Hagag et al, 1998). For example, scintiscanning may be helpful in differentiating a hyperplastic goiter from a follicular neoplasm (see below), whereas ultrasound provides accurate measurements of the size of nodules that are not considered as suitable for surgery and are followed clinically. Measurement of serum thyroid antibodies, which are not part of standard thyroid function tests, is the most useful blood test to confirm the diagnosis of **Hashimoto's thyroiditis**, which may sometimes present as single or multiple thyroid nodules (Wong and Wheeler, 2000) (see below).

We do not recommend routine use of FNA of small, nonpalpable masses found incidentally in patients, especially elderly patients, by ultrasound studies of neck performed for other reasons, for example, carotid artery studies. **Nonpalpable malignant lesions are rare, whereas nonpalpable benign thyroid nodules are very common.** Even if a small nodule is malignant, it usually is a low-grade papillary tumor of questionable clinical importance (Petez et al, 2001; Kimoto et al, 1999; Tambouret et al, 1999; Carmeci et al, 1998; Hagag et al, 1998; Lin et al, 1997).

In our work, we prefer to use **air-dried smears, stained with Diff-Quik**. The advantage of this technique is the short preparation and staining time and, despite opinions to the contrary, an excellent quality of nuclear features. With this technique, the colloid stains blue and, because of air drying, the cells are larger than in rapidly fixed smears. Still, rapidly fixed smears stained with Papanicolaou or hematoxylin-eosin are equally valuable and sometimes easier to interpret and to compare with histologic material, as illustrated in this chapter (Koss et al, 1992). Yang et al (1997, 2001) advocated the use of **ultrafast Papanicolaou stain** as advantageous in recognizing nuclear abnormalities in papillary carcinomas of the thyroid.

It must be stressed that regardless of method used, interpretation of cytologic material from the thyroid is not simple; it requires excellent material and a great deal of experience. Contrary to the belief of many clinicians that aspirating the thyroid is an easy and simple task, they often commit several cardinal mistakes: the aspirate takes too long and the samples are diluted with blood. Other errors include the use of larger caliber needles or "poking around the lesion" with the tip of the needle resulting in hemorrhagic necrosis. Therefore, to

ensure the best possible quality of smears, the FNA should be performed and interpreted by an experienced cytopathologist (Dwarakanathan et al, 1989).

Aspiration Biopsy Technique

Aspirations of the thyroid are best performed with 25 or 22 gauge needles by an **experienced operator**, preferably a cytopathologist. **The use of larger caliber needles is not recommended** because they cause more trauma and bleeding and result in unreadable bloody aspirates. Similarly, **more than one aspiration per nodule does not necessarily yield more diagnostic material** but rather causes more trauma to the patient. At the Englewood Hospital Medical Center, the aspiration biopsies are performed by a pathologist. The needle is attached to a 10-cc syringe and a Cameco aspiration gun. The slides are prepared, stained, and microscopically evaluated immediately while the patient waits and, only if the aspirate is not adequate for accurate diagnosis, is the patient re-aspirated. Thus, the number of aspirates can be tailored to the findings in the individual patient and, in most of them, one aspiration is adequate to yield a diagnosis (Aguilar et al, 1998).

The first step in the aspiration is to determine if a neck mass is, in fact, in the thyroid.

One should palpate the mass while the patient swallows. If it moves with swallowing, it is in the thyroid. If not, it is probably a lymph node or another adjacent structure.

The aspiration is best performed with the **patient supine and neck hyperextended**. To avoid inadvertent displacement of the gland during the biopsy, the patient is instructed to refrain from swallowing and speaking, but to continue breathing. After insertion, **the needle is rapidly moved in and out** to sample different parts of the palpable mass. Because the thyroid is richly vascularized, the actual aspirate must be performed as rapidly as possible, in about 1 to 2 seconds to avoid dilution of samples with blood. If **cyst fluid** is obtained, the aspiration should continue so long as the fluid keeps flowing.

There are usually no untoward effects from a correctly aspirated thyroid. Potential **side effects include pain, swelling, a hematoma, and acute infection**, all extremely rare occurrences.

Occasionally, an **acute infarction of a tumor**, most commonly a papillary carcinoma or a Hürthle cell tumor, can occur after aspiration (Kini, 1996; Pinto et al, 1996). This can cause exquisite pain, and may result in **difficulty in histologic diagnosis** of tumor in the surgically removed specimens (Baloch and LiVolsi, 1999; Ersoz et al, 1997; Vercelli-Retta et al, 1997).

Seeding of tumor cells in the needle track was reported in papillary carcinomas (Karwowski et al, 2002; Hales and Hsu, 1990). Two other reports of possible needle track seeding are not well documented (Panunzi et al, 1994; Wang et al, 1976).

Adequacy of Aspiration Biopsy

The issue of what constitutes an adequate thyroid sample has been a subject of debate for several years. Hamburger et al (1989), in a multi-institutional study, declared that **six clusters of epithelial cells** on two separate smears constitute an acceptable minimum of sampling adequacy. In many instances, however, **this criterion is unrealistic**. For example,

P.1150

pure colloid may be consistent with the diagnosis of benign colloid goiter and a pure population of macrophages may be diagnostic of a thyroid cyst or pseudocyst in a patient with past history of hemorrhage. In neither instance is the presence of epithelial cells required for diagnosis. Clearly, the issue depends on the type of lesion (cystic or solid) and the skill of the performer. It has been our experience that the latter is paramount.

Normal Structure of the Thyroid Gland

Anatomy

The thyroid gland is located in the neck, anterior to the trachea, and consists of two conical **lobes** connected by the isthmus. A third, smaller central lobe, the pyramidal lobe, is infrequently found. The lobes are divided by fibrous septa into **lobules**, each containing 30 to 40 follicles. The gland is enclosed in a true capsule that may adhere to the trachea and larynx. The thyroid is richly vascularized and has a high rate of blood flow.

Histology

The structural unit of the thyroid gland is the **follicle**, a closed, approximately spherical space lined with epithelial cells that vary in configuration from flat, to low cuboidal, to high columnar (Fig. 30-1C; see Fig. 30-3D). The height and configuration of the thyroid follicular cells reflect, to some extent, the functional activity. The cells are flat in inactive follicles and cuboidal or even columnar in active thyroid. In **hyperthyroidism**, the cells are **columnar** and their **cytoplasm** may be filled with **colloid-containing vacuoles**.

Figure 30-1 Benign thyroid. A. Large deposit of colloid surrounded by a few follicular cells. B. Pure colloid from a colloid nodule. Note the deep purple color and the "cracking artifact" in Diff-Quik stain. C. Histologic section of thyroid removed for colloid goiter corresponding to B. D. "C cells" immunostained for calcitonin by immunoperoxidase stain.

The follicles are filled with **colloid**, a homogenous eosinophilic substance. Variations in the density and staining properties of the colloid can also be ascribed some functional significance; **thin eosinophilic colloid** appears to be associated with functional activity, whereas **thick, markedly eosinophilic colloid** occurs in inactive follicles and in some malignant lesions (Fig. 30-1A,B).

For reasons unknown, the follicular cells may be transformed into **large cells** with **eosinophilic cytoplasm** and **large, often hyperchromatic nuclei**, known as **oncocytes** (bulky cells) or **Hürthle cells** (see Fig. 30-8). Such cells were first described by Hürthle in the thyroid of dogs. The role of these cells in the pathology of the thyroid is described below. The cytoplasm of oncocytes is crammed with **mitochondria**.

The thyroid also contains dispersed **calcitonin-producing cells** or **C cells** (Fig. 30-1D). Calcitonin is a hormone governing the metabolism of calcium and, hence, the skeletal system. The C cells may be the source of malignant tumors, known as **medullary carcinoma**, that may also secrete calcitonin, demonstrable by immunostaining (see below).

P.1151

Principal Lesions of the Thyroid

The principal lesions of the thyroid gland that may be identified in aspiration cytology are as follows:

- Cysts
- Goiters
 - Colloid goiter
- Thyroiditis
 - Acute
 - Subacute (deQuervain's)
 - Lymphocytic (Hashimoto's disease)
 - Riedel's Struma (fibrosing thyroiditis)
- Tumors
 - Follicular tumors
 - Follicular adenomas
 - Follicular carcinoma
 - Hürthle cell tumors
 - Hürthle cell adenoma
 - Hürthle cell carcinoma
 - Other carcinomas
 - Papillary and its variants
 - Medullary
 - Anaplastic (large- and small-cell types)
 - Malignant lymphomas
 - Rare malignant tumors

Metastatic tumors

It should be emphasized again that, although very specific diagnoses can be made by FNA, **the main purpose of the fine needle aspiration is to determine if the patient has a primary thyroid tumor, whether benign or malignant, requiring surgical excision, or has a nonneoplastic condition, such as a goiter or thyroiditis, which can be treated medically.** Large benign goiters, obstructing adjacent organs or disfiguring cosmetically, may require surgical intervention, regardless of cytologic findings. Statistical evidence strongly suggests that the use of aspiration biopsy has **markedly reduced the total number of thyroidectomies, whereas the proportion of carcinomas in the surgically treated population has increased significantly** (Koss et al, 1992).

Clinical Findings

Most patients are referred for FNA because of thyroid enlargement or the presence of a nodule or nodules. For reasons unknown, most patients are females. Age is not important because malignant lesions may occur in the very young and very old. However, it is important to know how long the abnormality has been present and whether its growth was slow, rapid, or sudden. This information may be of diagnostic significance because slowly growing multiple nodules or masses are less likely to be malignant than a more rapidly enlarging solitary nodule. A sudden increase in the size of the nodule suggests a hemorrhage. Still, none of these observations are conclusive and judgmental errors may occur in all situations prior to sampling of the lesion(s).

The Painful Thyroid

Of particular interest is the clinical observation of a thyroid illness presenting with pain as a primary complaint. In our experience, the differential diagnosis of a painful thyroid nodule in the **young or middle-aged patient** includes:

- Acute thyroiditis
- Cyst with acute hemorrhage
- Subacute or De Quervain's thyroiditis
- Infarcted Hürthle cell tumor (rare)
- Hashimoto's thyroiditis

In the elderly, a very painful thyroid nodule, or diffuse tenderness, should alert one to the possibility of an anaplastic carcinoma.

Goiters

The terms **goiter** or **struma** denote any **enlargement of the thyroid gland**, which may be diffuse or nodular. The three most common types are the **colloid goiter, inflammatory goiter or thyroiditis, and neoplastic goiter caused by benign or malignant tumors.**

Colloid Goiter

Synonyms: Adenomatous goiter, diffuse or nodular goiter, endemic goiter, multinodular goiter.

Histology

Colloid goiter is usually caused by hyperplasia of the thyroid gland **induced by iodine deficiency.** Its histologic appearance varies with the developmental stage of the disease. In the early stages, the changes are bilateral and there is a diffuse enlargement of the gland, made up of small follicles. Later on, some of the follicles may become distended and may coalesce to form **nodules**, with diameters ranging from less than 1 mm to several centimeters. Degenerative changes, such as **hemorrhage, necrosis, cysts** (actually **pseudocysts**) and **scar** formation, often occur in the nodules. The process may involve the entire gland or it may occur focally and produce a **solitary nodule**. On the scintiscan, such change is often labeled a "**cold nodule**," which is difficult to distinguish from a true neoplasm. For this reason, the **colloid goiter is the lesion most often referred for aspiration.**

Cytology

The make-up of a needle aspirate from colloid goiter depends on the type of the lesion. The aspirate may be **solid, semisolid, or fluid.** Solid or semi-solid aspirates often consist of **amber colored colloid** which, in Papanicolaoustained smears, appears as pink homogeneous material, usually surrounded by a few follicular cells (see Fig. 30-1A) and in Diff-Quik-stained smears, appears bluish-violet. On drying, the colloid may form a typical **cracked geometric pattern** (see Fig. 30-1B). This type of colloid is derived from distended inactive follicles containing dense central colloid (see Fig. 30-1C). Occasionally, aspirates of colloid goiters yield smears of **almost pure colloid with few follicular cells and/or macrophages.** Although such smears do not meet the proposed criteria of adequacy because they contain very few follicular cells, they are, in our experience, diagnostic of colloid goiter.

P.1152

In most cases, however, the smears also contain **small cuboidal follicular** cells, occurring either singly or in **flat sheets** wherein the **small, spherical nuclei** are evenly spaced and

honeycomb-forming cytoplasmic borders may sometimes be recognized (Fig. 30-2A). "Naked" **follicular cell nuclei** are often seen scattered throughout the smear and should not be confused with lymphocytes, which they resemble (Fig. 30-2B). **The nuclei of lymphocytes are usually slightly smaller** and upon close inspection, usually are surrounded by a very thin **rim of blue cytoplasm**, at least on one side of the cell. Sometimes entire follicles may be seen in the form of spherical clusters of cells, sometimes with a central deposit of colloid (Fig. 30-3). Swedish observers consider squashed follicles, wherein cell borders cannot be clearly seen as "**syncytial balls**" and characteristic of colloidal goiter (Fig. 30-3C). In posthemorrhagic nodules or cysts, **numerous macrophages**, usually containing phagocytized **hemosiderin granules**, may be observed (Fig. 30-4).

An important source of error is clusters or sheets of **spindle-shaped cells of the fibroblastic type**. This finding suggests that fibrosis has occurred within the goiter. Sometimes, **young, growing fibroblasts** from an area of active fibrosis are markedly **atypical**, with **enlarged, irregularly outlined nuclei** that may contain **large nucleoli** and abundant basophilic cytoplasm with multiple cytoplasmic extensions (Fig. 30-5). **Mitotic figures may also occur**. The atypical fibroblasts may be mistaken for malignant cells and must be interpreted within the context of the clinical situation and other cytologic findings. It is of note that, very rarely, **exuberant fibrosis may also occur in papillary thyroid carcinomas** (Chan et al, 1991; Us-Krašovec and Golough, 1999).

A fairly high proportion of aspirations in colloid goiter yield variable amounts of **fluid** which usually indicates **degenerative cystic changes** (see below). The fluid may be clear, yellow, or brown in color, the latter indicative of a prior hemorrhage. Although the microscopic examination of the cyst fluid is seldom useful, it is mandatory because, occasionally, **cystic thyroid carcinomas** may masquerade as cystic goiters.

Over time, goiters often become nodular, sometimes in the form of a **solitary nodule**, usually arising from focal hyperplasia. Such nodules, often of **adenomatous nature**, usually **cannot be reliably differentiated** on clinical or ultrasonographic grounds from a "**true**" **adenoma or carcinoma**. As a general rule, **smears from nonneoplastic nodules contain much colloid and few cells**. By contrast, in aspirates from **neoplastic lesions**, there is **little colloid and numerous cells**. However, **on rare occasions, aspirates of hyperplastic adenomatous nodules are also very cellular and may be very difficult to interpret**. Certain features of the smears are sometimes helpful. Thus, the follicular cells tend to form a dispersed pattern in adenomatous goiter, rather than tight clusters or rosettes as in true adenomas. Also, "**balls**" of **follicular cells**, representing squashed whole follicles (see Fig. 30-3), are more characteristic of colloid goiter than of follicular adenomas. One has to gauge all these features in order to arrive at a correct interpretation. Although most cases are straightforward, **the distinction between a hyperplastic adenomatous nodule and follicular neoplasm can be difficult, as it is in histological sections** (Zacks et al, 1998; Busseniers and Oertel, 1993). In such cases, the interpretations and recommendations may include a course of suppression therapy with exogenous thyroid hormones or repeat FNA. If the mass does not regress, a surgical removal must be considered. In such a case, a scintiscan may be helpful. If the mass is "**cold**," **one would favor surgery rather than medical therapy**, since a "cold" nodule would more likely be a true tumor.

Figure 30-2 Benign follicular cells. A. Follicular cells forming flat sheets with "honeycomb" pattern. B. Clusters of normal follicular cells with many dispersed cells in the background.

Cysts

Histology

Cystic lesions constitute 10% to 30% of all thyroid nodules, depending on the population studied. Nearly all thyroid cysts are **pseudocysts** that develop in nodular goiters or in adenomas as a consequence of degenerative tissue break-down or a hemorrhage.

Pseudocysts are usually formed by fusion of adjacent distended follicles. They are usually lined by flattened or cuboidal cells of thyroid epithelium and may undergo focal **squamous metaplasia**. The very uncommon **true cysts** derived from the remnants of the **thyroglossal**

duct are located in the midline, usually above the thyroid, and are lined by either cylindrical or squamous epithelium (see below). A case of an intrathyroid lymphoepithelial cyst of probable branchial origin was described by Apel et al (1994). It must be stressed that **some malignant tumors, particularly papillary carcinomas, are often partly cystic**.

Figure 30-3 Thyroid follicles in benign goiters. *A.* Several colloid-filled follicles with dispersed follicular cells in the background. *B. Left,* An entire three-dimensional thyroid follicle. *Right,* Broken up follicle with a small deposit of colloid in the center. *C.* Tightly packed, compact thyroid follicle, commonly observed in benign colloid goiters. Note the abundant cytoplasm seen under high magnification with Diff-Quik stain. The term “syncytial balls” has been attached to this formation. *D.* Histologic section of colloid goiter. Note the variability in the size of the acini. (*C:* Courtesy of Dr. Sixtén Franzén, Stockholm, Sweden.)

Cytology

Depending on their size, aspirated cysts or pseudocysts of the thyroid yield a few drops to several milliliters of fluid that may be clear, turbid, yellow, brown, or bloody. Preparation of smears may require centrifugation of the fluid. The smears of fluid aspirated from a cyst with a **recent hemorrhage** contain mainly **blood** and clusters of **well-preserved follicular cells**. In cysts aspirated some weeks after the hemorrhage, the few follicular cells may show **degenerative nuclear changes** in the form of **smudging** or **hyperchromasia** and are accompanied by **hemosiderin-laden macrophages** and by inflammatory cells (see Fig. 30-4). Hemosiderin stains **blue or black on Diff-Quik stain** and **brown in Papanicolaou stain**. The sediments of the clear or yellowish fluids obtained from old hemorrhagic cysts usually contain only a few macrophages.

In **degenerative cysts**, the smears are usually characterized by numerous **macrophages with foamy cytoplasm, containing cell debris** (see Fig. 30-4A) that may be accompanied by few inflammatory cells. Occasionally, a few clusters of follicular cells may be found in the smears.

If after aspiration of the cyst content, no residual palpable lesion is found, further therapeutic procedures may be avoided. In contrast, **if after the evacuation of the fluid, a palpable lesion remains, the aspiration should be repeated in order to rule out the possibility of a tumor masquerading as a cyst**. In the sediment of the fluid aspirated from **cystic papillary carcinoma**, **calcified psammoma bodies may be observed as the only abnormality**. Thus, the **presence of calcified particles in cyst fluid should be interpreted with great caution** and mandates further exploration of the lesion. Other unusual cytologic findings, such as the presence of compact clusters of follicular cells, also deserve attention, as they may signal the presence of a thyroid neoplasm.

Thyroiditis

Thyroiditis, or inflammation of the thyroid gland, comprises a large group of diseases that range from acute suppurative

P.1154

thyroiditis to chronic inflammatory processes. The term also includes a number of transient disorders such as **postpartum thyroiditis** and **drug-induced thyroiditis** (recent review in Pearce et al, 2003). Only the common forms of thyroiditis should be sampled by FNA and they are discussed below.

Figure 30-4 Macrophages in colloid goiter. *A*: A macrophage containing in its cytoplasm, numerous fragments of clear material, most likely fat. *B*: Numerous large macrophages with faintly vacuolated cytoplasm next to sheets of follicular cells. *C*: Hemosiderin containing macrophages from a hemorrhagic cyst of the thyroid. *D*: Follicle filled with colloid containing numerous macrophages. (*A, C*: High magnification; *B*: Diff-Quik stain.)

Acute thyroiditis is uncommon. It presents as an erythematous, markedly tender, diffuse process involving the thyroid accompanied by fever and generally does not represent a clinical diagnostic challenge. The aspiration biopsy, very rarely performed, yields follicular cells, neutrophils, and macrophages. Sodhani (1989) reported the presence of **microfilariae** in such a case.

Figure 30-5 Fibrous reaction in colloid goiter. *A*: Cluster of elongated cells, corresponding to fibroblasts. *B*: Numerous elongated cells, some with giant nuclei, in reactive fibrosis in a thyroid scar. (*A*: Diff-Quik stain; *B*: high magnification.)

P.1155

Figure 30-6 Subacute thyroiditis. The smear contains a large multinucleated giant cell surrounded by debris. (Diff-Quik stain.)

With the onset of AIDS, thyroiditis caused by the parasite *pneumocystis carinii* has been observed (Guttler and Singer, 1988). Several cases of this disease were diagnosed by aspiration cytology of the thyroid (summary in Keyhani-Rofagha and Piquero, 1999). The morphology of the parasite is discussed at length in Chapter 19.

In **granulomatous (subacute, de Quervain's) thyroiditis**, the thyroid is slightly to moderately

enlarged and tender on digital examination. The patient frequently gives a history of a recent upper respiratory infection or a viral syndrome. The aspirate contains **follicular epithelial cells, epithelioid cells, and giant cells of Langhans' type**, together with lymphocytes, plasma cells, and occasionally some granulocytes (Fig. 30-6) (Shabb et al, 1999; Garcia Solano et al, 1997; Löwhagen and Willems, 1981).

Hyperthyroidism

Hyperthyroidism, known in its classical form as **Graves' disease**, consists of a goiter, exophthalmos, tremor, and flushed skin. It can be associated with a diffuse goiter or a single hyperplastic thyroid nodule. Aspiration biopsies are practically never performed in diffuse toxic goiter but may be performed on solitary nodules.

Figure 30-7 Hyperthyroidism (Graves' disease). *A* Follicular cells with eosinophilic cytoplasmic vacuoles in Diff-Quik stain, characteristic of hyperthyroidism. The term “flare cells” has been often attached to this phenomenon. *B*. Section of thyroid in hyperthyroidism, showing scalloped colloid and tall, vacuolated follicular cells.

Aspirates of **untreated hyperplastic thyroid** may contain a small number of **large follicular cells** with slightly enlarged nuclei and abundant cytoplasm with large round **vacuoles** of variable sizes containing deposits of **colloid**. In Diff-Quik and other hematologic stains, the cytoplasmic deposits of colloid stain **bright red**, hence the name “**flare cells**” (Fig. 30-7). Such cells occur singly or in small clusters, but rarely in large sheets (Myren and Sivertssen, 1962).

Centeno et al (1996) noted scarring of the thyroid and subsequent problems of interpretation of aspirates from patients treated with radioactive iodine for Graves' disease.

Lymphocytic Thyroiditis or Hashimoto's Disease

Clinical Data and Histology

This is the most common form of thyroiditis observed in clinical practice. It most often affects **middle-aged women** and is thought to be an autoimmune disease. **Antithyroid antibodies are often elevated** in this condition and thyroid function may be reduced, normal, or elevated. Both lobes of the thyroid are usually affected, diffusely enlarged and firm, but asymmetry may occur, with **localized nodular enlargement** (Wong and Wheeler, 2000). In histologic sections, the thyroid is infiltrated with lymphocytes that may also form lymph follicles with germinal centers (see Fig. 30-8D). The acini are often destroyed or atrophic (see Fig. 30-9D). **A major component of the disease is the presence of oncocytes (Hürthle cells)**. The oncocytes may line glandular structures or form solid sheets of various sizes. The characteristic features of **oncocytes, namely, abundant, eosinophilic, granular cytoplasm and large, often pyknotic nuclei** of variable sizes, are usually well represented in Hashimoto's thyroiditis (see Fig. 30-9C,D). Sometimes the Hürthle cells appear as **single large cells** in otherwise normal follicular epithelium. The term **Askanazy cells** is sometimes used to describe this feature. Rarely, **psammoma bodies** may be seen in Hashimoto's thyroiditis (Dugan et al, 1987).

Thyroid carcinomas and malignant lymphomas

may occur in Hashimoto's thyroiditis. There is a misperception that malignant lymphoma is the most common tumor seen in Hashimoto's thyroiditis. In fact, from 5% to 10% of patients with this disease will develop **papillary carcinoma**, and less than 1% develop malignant lymphoma (Carson et al, 1996).

A recently described clinical entity known as **subchemical hypothyroidism** with antibody-negative chronic thyroiditis, usually occurs in women with symptoms of fatigue, malaise, and hair loss (Wikland, et al, 2003; Wikland et al, 2001). These women often have negative physical examinations and medical work-ups, but are found to have chronic thyroiditis on FNA of their thyroid gland, if the astute clinician considers it in his or her differential diagnosis. The symptoms usually respond dramatically to oral levothyroxine.

Cytology

The aspiration smears are characterized mainly by the presence of **a mixture of lymphocytes** and oncocytes or **Hürthle cells** in various proportions. In some cases, the aspirates are dominated by **lymphocytes** at various stages of maturation, and the smear may

P.1156

resemble an aspirate of a hyperplastic lymph node (Fig. 30-8A). Further search will usually reveal the presence of **oncocytes** and **scattered follicular cells** in clusters (Fig. 30-8B). We have observed a case of Hashimoto's disease in which the pattern was mistaken for a metastatic carcinoma to lymph node (Koss et al, 1992). In other cases, the presence of **oncocytes is dominant**. In aspirates, these large cells form sheets or gland-like structures. The striking, abundant, eosinophilic and granular cytoplasm and the **variability in nuclear sizes** are characteristic (Fig. 30-9A,B). Sometimes the **nuclei contain fairly large nucleoli**, and, very rarely, intranuclear cytoplasmic inclusions (see Fig. 30-8C). Because of nuclear abnormalities, these cells can be mistaken for malignant cells. On further search, lymphocytes and follicular thyroid cells can be observed. **On rare occasions, the follicular cells in clusters may mimic a papillary carcinoma** (MacDonald and Yazdi, 1999). Still less common is the presence of psammoma bodies (Dugan et al, 1987). These, fortunately very rare findings, may lead to an erroneous diagnosis of papillary carcinoma.

Figure 30-8 Hashimoto's thyroiditis. A. Smear pattern with lymphocytic predominance. The lymphocytes are in various stages of maturation. This pattern may be misinterpreted as a malignant lymphoma. B. Scattered lymphocytes and large Hürthle cells. C. A Hürthle cell showing an intranuclear cytoplasmic inclusion. D. Histologic pattern of Hashimoto's thyroiditis showing lymphocytic deposit and follicles lined by eosinophilic Hürthle cells. (A,B: Diff-Quik stain.)

As a general rule, the cytologic features of Hürthle cells in Hashimoto's thyroiditis can be differentiated from a Hürthle cell tumor. In **thyroiditis** the oncocytes are **large, atypical, and pleomorphic**, whereas **Hürthle cell tumors** usually show **monotonous cells**, as is the case in histologic sections (see below) (Chen et al, 1998; Ravinsky and Safneck, 1988).

P.1157

Further, the presence of abundant lymphocytes is very uncommon in Hürthle cell tumors.

Figure 30-9 Hashimoto's thyroiditis. A,B. Hürthle cells stained with Diff-Quik (A) and, after fixation, with Papanicolaou stain (B). The difference in size of the cells in the two modes of smear preparation is well shown. Note the variability in the sizes of the nuclei in the benign Hürthle cells. C. Section of the thyroid gland in Hashimoto's disease showing lymphocytic infiltrate and Hürthle cells lining the adjacent acini. D. Section of the thyroid with follicular atrophy in Hashimoto's thyroiditis.

The recognition in cytologic samples of either **carcinoma or lymphoma**, occurring in Hashimoto's thyroiditis, may be exceedingly difficult. If a carcinoma is suspected, a **surgical biopsy** should be suggested. If a lymphoma is suspected, **flow cytometry studies** performed

on the aspirate may help in determining a definitive diagnosis without having to resort to surgery.

Riedel's Struma

Riedel's struma is a **sclerosing inflammatory disorder** of the thyroid gland, sometimes associated with a similar tissue reaction in the mediastinum, retroperitoneum, and orbit. On aspiration, the thyroid gland feels very rubbery or firm and the yield from a needle aspiration is nil or very scanty, sometimes containing only a few fibroblast-like cells. This disorder **must be distinguished from infiltrating carcinoma**, in which a fairly rich cell population would be obtained.

Neoplastic Lesions

Classification

In textbooks and other teaching materials pertaining to the thyroid gland, it is customary to separate benign (adenomas) from malignant lesions (carcinomas). However, because the **histologic and cytologic differences between the benign and malignant variant of the follicular cell tumors and Hürthle cell tumors are subtle** and the behavior of these lesions is usually difficult to predict either on histologic or on cytologic evidence, these lesions will be discussed in two categories: **follicular tumors and Hürthle cell tumors**, comprising both the benign and the malignant variants. Other malignant tumors of the thyroid are discussed further on. A brief summary of the key cytologic features of the principal types of thyroid neoplasms is shown in Table 30-1.

Follicular Tumors

Histology

Follicular adenoma is a benign **encapsulated** tumor composed of follicular cells **without invasion** of capsule or vessels. Adenomas are, for the most part, composed of **smaller medium-sized follicles containing variable amounts of colloid** (see Fig. 30-10D), but can be also **solid** or **trabecular**. In the latter two forms of adenomas, the follicular cells do not produce colloid. **Mixed types of adenomas** with foci of varied architecture, including foci of Hürthle cells, also occur. **Significant abnormalities of nuclei** in the form of enlargement and hyperchromasia may be observed in all types of adenomas.

P.1158

TABLE 30-1 KEY MORPHOLOGIC FEATURES OF DIFFERENTIAL DIAGNOSIS AMONG COMMON THYROID TUMORS

	Follicular cells	Hürthle cells	Clearly malignant cells	Lymphocytes	Colloid	Multinucleated giant cells	Psammoma bodies	Comments and sources of error
Follicular neoplasms	Larger than normal in numerous aggregates; coarse chromatin pattern	Scanty	Uncommon, except in high grade carcinomas	Absent	Scanty	Absent	Rare	Follicular adenoma usually cannot be distinguished from follicular carcinoma
Hürthle cell tumors	Scanty	Dominant, usually monotonous	Uncommon in high grade tumors	Scanty	Scanty	Absent	Exceptional	Hashimoto's thyroiditis may mimic Hürthle cell tumor
Papillary carcinoma	Clearly enlarged, follicular cells in 3 dimensional papillary clusters; ground-glass nuclei, nuclear grooves and cytoplasmic nuclear	Rare	In tall cell variant	Scanty, except in Warthin's type	Condensed droplets	Common	Common	Follicular variant may be confused with follicular neoplasms

inclusions								
Medullary carcinoma	Incidental	Absent	Small, large or spindly-forming amyloid	Rare	Absent	Occasional in large cell type	Absent	Differential diagnosis with metastatic cancer
Undifferentiated carcinoma	Absent	Absent	Small or large	Absent		May be dominant in large cell tumor type	Absent	Differential diagnosis with metastatic cancer and in the presence of multinucleated giant cells with subacute thyroiditis (DeQuervain)

P.1159

Exceptionally, follicular adenomas may be composed of small follicles lined by epithelial cells with **cytoplasm filled with colloid** pushing the small, hyperchromatic nuclei to the periphery (**signet-ring adenomas**). The tumor cells resemble **signet ring cells**, except for small nuclei (Koss et al, 1992).

Follicular carcinomas are solid tumors of the thyroid that in their **well-differentiated form** are similar to adenomas and are composed of **small- to medium-sized follicles**, usually containing some colloid. The cells lining the follicles may be somewhat larger than normal and the individual nuclei hyperchromatic but **significant cell abnormalities are rare, and the differences between a follicular adenoma and a well-differentiated carcinoma are often illusory** (see Figs. 30-10D and 30-11B). **In such cases, only invasion of tumor capsule, adjacent thyroid, or blood vessels constitutes evidence of malignant behavior.** Even under those circumstances, the opinion of experts may differ as to whether the tumor is an adenoma or carcinoma (Baloch et al, 2000). DNA ploidy determination is not helpful because follicular carcinoma may be diploid and follicular adenomas aneuploid (Greenebaum et al, 1985). Still, **even the very well-differentiated carcinomas may form distant metastases that morphologically resemble normal thyroid**, sometimes described in the past as “**benign metastasizing struma**” (see Fig. 30-13). Tickoo et al (2000) pointed out that, in about one-third of thyroid cancers metastatic to the bones, the metastatic deposit may be better differentiated than the primary tumor.

Less well, or poorly, differentiated follicular carcinomas are a mixture of follicles lined by distinctly abnormal cells and **solid sheets of neoplastic cells** with enlarged, atypical nuclei and prominent nucleoli (see Fig. 30-12D). These tumors have a less favorable prognosis than the well-differentiated variety. **Clear cell carcinomas** of the thyroid are variants of follicular carcinoma.

Cytology

In general, the aspirates of follicular neoplasms are **cellular and have an abundant population of cells with little colloid**. Smears of **follicular adenomas** usually contain **numerous clusters** of follicular cells, usually arranged in **flat follicular or papillary structures or flat, tight aggregates**. The tumor cells may also form **small, rosette-like acinar clusters, containing inspissated colloid** (Fig. 30-10). Single follicular cells and nuclei stripped of cytoplasm ("naked nuclei") are scattered throughout the smear. **Anisonucleosis may be present**. The nuclear chromatin is uniformly distributed and the **nucleoli are small and barely**

P.1160

visible. Small, indistinct intranuclear clear inclusions may occur and do not necessarily indicate a malignant tumor (see Fig. 30-10B). The papillary configuration of some of the colloid-free clusters may be **reminiscent of papillary carcinoma**. However, the clusters in papillary cancer are often multilayered and complex and show specific nuclear abnormalities that are not evident in follicular tumors (see below). Aspiration smears from **follicular carcinomas** are also **highly cellular with little or no colloid**. The cells occur primarily in **clusters** and are often arranged in **follicle-like structures**. Thus, they may closely resemble the cytologic presentation of follicular adenoma. In **well-differentiated follicular carcinoma, cellular atypia may be minimal**, and the general impression from the smear may suggest a benign lesion, rather than a carcinoma (Fig. 30-11). Therefore, **in such cases, the cytologic diagnosis should be "follicular neoplasm or tumor,"** clearly indicating that **surgical excision and histologic examination is mandatory** for a reliable differential diagnosis between follicular adenoma and a well-differentiated carcinoma.

In less well-differentiated forms of follicular carcinoma, **nuclear atypia** is present but it rarely reaches high levels of abnormality. The **nuclei may vary in size and show some hyperchromasia** (Figs. 30-12A and 30-13A). Rarely, **nuclear pallor and small intracytoplasmic nuclear inclusions** (nuclear holes) may be noted (Fig. 30-13A). Particularly valuable is the presence of **prominent, large nucleoli within the follicular cells** (see Fig. 30-12B). In such cases, the **cytologic diagnosis of follicular carcinoma may be justified but we still prefer to sign out these cases as "follicular neoplasm-excision recommended"** because some **follicular neoplasms with severe atypia are encapsulated and their malignant nature is uncertain**. In such cases, the histologic classification may vary between "atypical follicular adenoma" and "follicular carcinoma without invasion," depending on the preference of the pathologist. Still, in some of these cases, recurrent or even metastatic tumor may be observed, sometimes many years after the removal of the primary (Fig 30-13B).

Figure 30-11 Follicular carcinoma. *A.* Aggregates of follicular cells with nuclear enlargement and small intranuclear cytoplasmic inclusions. The colloid is scanty. *B.* Periphery of the follicular tumor showing invasion of capsule. *C.* Histologic section of the same tumor composed of sheets of follicular cells with intranuclear cytoplasmic inclusions. (*A:* Diff-Quik stain.)

Hürthle Cell Tumors (Oxyphilic or Oncocytic Adenoma and Carcinoma)

Histology

These usually encapsulated tumors are composed of sheets and follicles composed of **large, eosinophilic Hürthle cells with granular cytoplasm**. **Intracytoplasmic lumens**, containing thyroglobulin, have been observed in these cells (Gonzales-Campora et al, 1986). The follicles contain little or no colloid (Fig. 30-14D). **Nuclear abnormalities** in the form of large, irregular, hyperchromatic nuclei **are common**. The configuration of nuclei has no prognostic significance because most such tumors are encapsulated

P.1161

and do not recur or metastasize after careful surgical removal. A **papillary variant of Hürthle cell tumor** and a variant of papillary carcinoma composed of Hürthle cells with lymphoid stroma (**Warthin's-like tumor**) are discussed below with papillary carcinomas. **Fewer than**

10% of the Hürthle cell tumors invade the capsule, blood vessels, and adjacent organs and, therefore, must be considered malignant (Fig. 30-15D). Because of their unpredictable behavior, surgical removal of these tumors is the treatment of choice (Nguyen et al, 1999). Infarction of these tumors is an infrequent, but known, complication of FNA (Kini, 1996; Pinto and Mandreker, 1996).

(*A,B:* Diff-Quik stain; *B:* high magnification.)

Cytology

In contrast to Hashimoto's thyroiditis, **where the Hürthle cells are dispersed or form small clusters and show considerable nuclear variability**, in **Hürthle cell neoplasms, the cells are usually of uniform size and shape and form tight aggregates or clusters**. Small, basophilic **cytoplasmic granules** are better seen in air-dried smears stained with hematologic stains. The **nuclei are large, vary in size, and may contain visible nucleoli** (see Figs. 30-14 and 30-15). Intracytoplasmic nuclear inclusions may be observed (Koss et al, 1992). Galera-Davidson (1997) and Yang and Khurana (2001) observed that the presence of **intracytoplasmic lumens** containing thyroglobulins and capillary vessels (named **transgressing vessels**) in aspirates is more likely to occur in the malignant variant of a Hürthle cell lesion than in a benign tumor or Hashimoto's thyroiditis. The most important point of differential diagnosis of Hürthle cell tumor is Hashimoto's thyroiditis with little or no lymphocytic component.

Papillary Carcinoma and Its Variants

Clinical Data and Histology

Papillary carcinomas are the most common malignant tumors of the thyroid, usually presenting as a palpable **thyroid nodule** that does not absorb radioactive iodine and, therefore, is "**cold**" on scintiscan (see Fig. 13-17A). The tumors occur **mainly in women** but have been observed in **men** and in **children**, the latter either spontaneous or after exposure to radioactive elements, such as the recent Chernobyl disaster (Tronko et al, 1999).

The **histologic structure** of these tumors is fairly characteristic: anastomosing, papillary **branches of the tumor** are lined by cells with **opaque or clear homogeneous nuclei**, sometimes showing visible nucleoli. Clear, sharply demarcated, **intranuclear cytoplasmic inclusions and psammoma bodies** are commonly observed. The connective tissue core of the tumor branches is richly vascularized (see Figs. 30-16D and 30-17D).

This group of tumors may have unusual clinical presentation. Although, in most instances, a nodule is observed in the thyroid, **the first clinical manifestation of the tumor may be a metastasis to a lymph node of the neck** from a small, occult primary tumor. Such metastases may be cystic. The faulty term "lateral aberrant thyroid" has sometimes been used in the past to describe these situations (recent reviews in Coleman et al, 2000; Verge et al, 1999).

The **behavior** of papillary carcinomas is unpredictable. Most of the tumors are indolent and do not recur or metastasize after removal, even in the presence of metastases to neck lymph nodes. In some cases, however, widespread metastases to lung, the skeleton, central nervous system and, occasionally, other organs may be observed.

P.1163

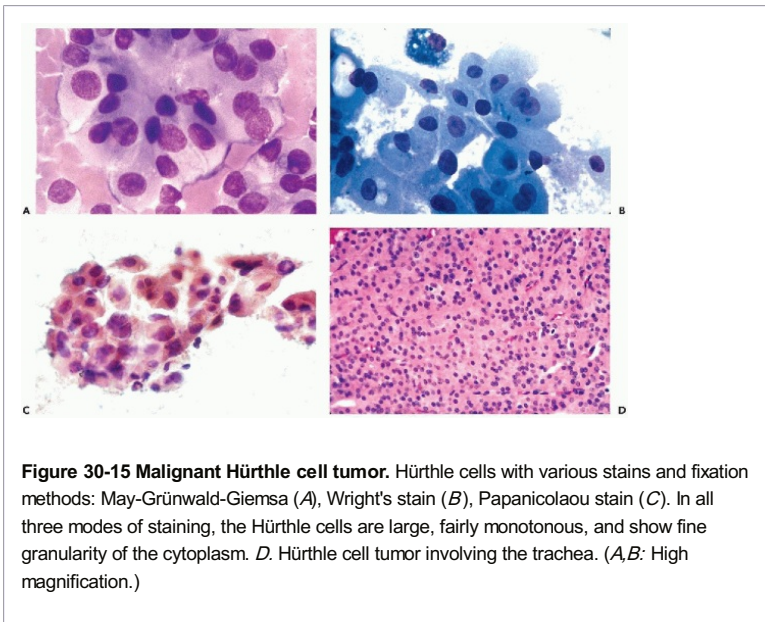

Figure 30-15 Malignant Hürthle cell tumor. Hürthle cells with various stains and fixation methods: May-Grünwald-Giemsa (A), Wright's stain (B), Papanicolaou stain (C). In all three modes of staining, the Hürthle cells are large, fairly monotonous, and show fine granularity of the cytoplasm. D. Hürthle cell tumor involving the trachea. (A,B: High magnification.)

Several **variants** of the papillary carcinoma have been described. The most important are tumors composed of **large, columnar cells (tall-cell variant)** with poor prognosis, and the **follicular variant** in which the structure of the tumor resembles follicular carcinoma, except for the **characteristic nuclear features and behavior similar to papillary carcinomas**. There is also a variant **resembling Warthin's tumors** of the salivary glands. These and other variants are discussed below.

The **differential diagnosis** of papillary carcinoma must include a rare type of benign thyroid tumor, the **hyalinized trabecular adenoma that has many cytologic features of papillary**

carcinoma: intranuclear cytoplasmic inclusions, nuclear grooves, and occasional psammoma bodies (Carney et al, 1987). There is no description of the cytologic presentation of this tumor but it may be assumed that it would mimic papillary carcinoma. Koss et al (1992) also reported a case of **Hashimoto's thyroiditis** with papillary clusters of follicular cells mimicking the pattern of papillary carcinoma that was not present in extensively studied excisional thyroid biopsy.

Cytology

Needle aspirates from papillary carcinomas are usually rich in cells. The cells may be dispersed, arranged in **complex, anastomosing papillary fragments, follicular structures,** or in **monolayered sheets generally free of colloid.** The presence of the **complex papillary clusters that can be observed under low power of the microscope is diagnostic of the tumor** (Figs. 30-16A,B and 30-17B). **Calcified psammoma bodies** are common (Fig. 30-18C). It must be noted, though, that **calcified structures mimicking psammoma bodies** may sometimes occur in normal thyroids, chronic thyroiditis, and sometimes in other types of thyroid tumors (Ellison et al, 1998; Dugan et al, 1987).

The **tumor cells**, although similar to normal follicular cells, are usually **perceptibly larger.** The **cytoplasm** is usually basophilic and opaque; on close inspection, one may observe small, discrete **vacuoles.** Hirokawa et al (2000) reported that these vacuoles represent dilated endoplasmic reticulum in electron microscopy and hypothesized that the change is degenerative in nature.

Next to papillary configuration of cell clusters, nuclear abnormalities are crucial in cytologic recognition of papillary carcinoma. In general, **the nuclei of cancer cells are larger** than those of normal follicular cells. Still, the nucleocytoplasmic ratio is not perceptibly altered. The most common nuclear features are the somewhat opaque **"ground-glass"** nuclei, with the nuclear chromatin pushed

P.1164

to the periphery, and **small central nucleoli** (see Fig. 30-20B), as first reported by Pedio et al (1981). The characteristic, sharply demarcated **intranuclear cytoplasmic inclusions**, first reported by Söderström and Björkland (1973), can be recognized on either Diff-Quik or Papanicolaou stains (see Fig. 30-16B,C). Another feature of note is nuclear **folds or grooves** in finely granulated, **opaque nuclei** of tumor cells (Fig. 30-18A) (Kini, 1996; Bhambhani et al, 1990; Deligeorgi-Politis, 1987). Small, isolated, **approximately spherical small deposits of dense inspissated colloid** were thought by Löwhagen (1981) to be very characteristic of papillary carcinoma (Fig. 30-19A,B).

Figure 30-16 Papillary carcinoma of thyroid. *A.* Multilayered, complex papillary arrangement of follicular cells diagnostic of papillary carcinoma. *B.* Sheet of follicular cells showing somewhat enlarged nuclei and intranuclear cytoplasmic inclusions. One of the inclusions is double. *C.* Oil immersion to show tumor cells with a conspicuous intranuclear cytoplasmic inclusion. Note the sharp edge of the inclusion. *D.* Histologic section of papillary carcinoma corresponding to *A.* (*A:* Diff-Quik stain.)

Perhaps the most valuable diagnostic feature is the intracytoplasmic nuclear inclusions. If **more than three true intranuclear inclusions** are seen in enlarged nuclei on a single aspirate of a thyroid nodule, the finding is **almost pathognomonic for a papillary carcinoma** (Yang and Greenebaum, 1997). These inclusions must be crisp, with clear, rather than hazy, borders. In our opinion, the inclusions are so characteristic that even if they are seen in an aspirate with no other features of a papillary carcinoma, a **surgical excision** should be considered. Conversely, if one suspects a papillary carcinoma, an exhaustive search for intranuclear inclusions should be undertaken. It should be noted that intranuclear inclusions may also be observed in other types of thyroid cancer and in other tumors, such as malignant melanomas, meningiomas, and bronchioloalveolar carcinoma. Very rarely, such inclusions may be observed in benign Hürthle cells (see Fig. 30-8C). This type of **true, intranuclear inclusions** should not be confused with poorly demarcated areas of central clearing that may occur in benign thyroids (see Fig. 10-

30B).

Multinucleated giant cells of the foreign body type (see Fig. 30-18B) are very common in smears of papillary carcinomas. In general, the giant cells are adjacent to papillary or monolayer fragments of tumor cells. The presence of such cells in an aspirate should trigger the suspicion of such a tumor (Guiter and DeLellis, 1996). Aspirates of other entities, particularly **subacute thyroiditis**, also contain giant cells, but will also be associated with other clinical and cytological findings (see above). Khurana et al (2001) noted that in **children and adolescents, benign solitary hyperplastic thyroid nodules** may lead to an erroneous diagnosis of papillary carcinoma, either in cytologic or histologic material (LiVolsi, 1990).

Variants of Papillary Carcinoma

Several histological subtypes of papillary carcinoma have been described. Except for the **tall-cell variant**, which has a much worse prognosis than the typical papillary carcinoma,

P.1165

the other subtypes do not appear to have any additional prognostic significance. However, the histologic variants have their cytological counterparts and their recognition is possible with a relatively small margin of error (Nair et al, 2001). These variants include:

Figure 30-17 Papillary carcinoma of thyroid. A. Scintigram of thyroid in a 34-year-old woman showing a "cold nodule" in the upper part of the right lobe. B. Corresponding aspirate showing a large papillary cluster of tumor cells with a central capillary vessel. C. A flat sheet of tumor cells closely resembling normal acinar cells, except for slight nuclear enlargement and the presence of nucleoli. D. Section of the thyroid gland corresponding to A-C.

- Cystic papillary carcinoma
- Follicular variant of papillary carcinoma
- Tall-cell variant of papillary carcinoma
- Warthin's-like variant of papillary carcinoma
- Diffuse sclerosing variant of papillary carcinoma in childhood

Other extremely rare forms of papillary carcinoma are morphological curiosities that deserve only a brief mention, such as **micropapillary**, **macrofollicular**, **carcinoma with nodular fasciitis-like stroma**, **clear cell**, and **oxyphil or oncocytic** (Yang et al, 1999; Carpi et al, 1999; Chan et al, 1991; Us-Krasovec and Golough, 1999; Hirokawa et al, 1998; Doria et al, 1996).

Cystic papillary carcinoma is a clear example why all fluids aspirated from the thyroid should be examined microscopically (Goellner and Johnson, 1982). The aspirates of cystic papillary carcinomas frequently yield **clear fluid**. In our experience, **the cells floating in the fluid** are best retrieved by **tapping the hub of the needle**, where the cells become trapped, backwards onto the slide. The tumor cells obtained with this simple maneuver are often of sufficient quantity to permit a diagnosis. Sediment of the fluid may also provide diagnostic material.

The **microscopic findings** in cystic papillary carcinoma are similar to the solid forms of the classical papillary carcinomas, **but differentiated cells with small nuclei are rather prominent**.

Occasionally, **metastatic** papillary carcinomas of the thyroid will present as a **cystic lesion in the lateral neck**. The presence of malignant cells in the sediment, confirming the diagnosis of a metastatic papillary carcinoma, will almost always lead to the discovery of an **occult primary papillary carcinoma in the ipsilateral thyroid lobe**. In a case illustrated by Koss et al (1992), the large thyroid cancer cells had a vacuolated cytoplasm, resembling **signet-ring cells** and were accompanied by a few cells with squamoid features. Sometimes, the **presence of a psammoma body** in the fluid may suffice to suspect the presence of a papillary carcinoma in

the thyroid (Coleman et al, 2000; Verge et al, 1999; Koss et al, 1992).

Follicular Variant of Papillary Carcinoma

Simply stated, the follicular variant of papillary carcinoma has the low-power **microscopic appearance of a follicular**

P.1166

neoplasm and the nuclear features of a papillary carcinoma. Intranuclear cytoplasmic inclusions and “ground glass” nuclei with micronucleoli are the morphological clues to the diagnosis of this entity (Fig. 30-20A-C) (Baloch et al, 1999; Goodell et al, 1998; Shemen and Chess, 1998; Hugh et al, 1988; Chem and Rosai, 1977).

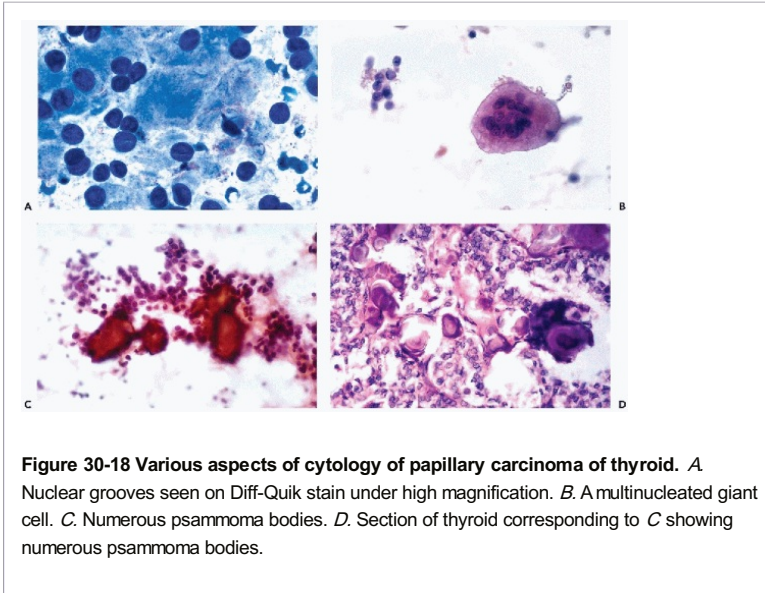

Figure 30-18 Various aspects of cytology of papillary carcinoma of thyroid. *A.* Nuclear grooves seen on Diff-Quik stain under high magnification. *B.* A multinucleated giant cell. *C.* Numerous psammoma bodies. *D.* Section of thyroid corresponding to *C* showing numerous psammoma bodies.

Tall-Cell Variant of Papillary Carcinoma

This uncommon tumor occurs predominantly in elderly women and has a documented **aggressive clinical behavior**. When first seen, it may present as a large thyroid mass with regional lymph node metastases. Cytologically, the **tumor cells are dispersed, large, sometimes of columnar configuration, with eccentric nuclei, and eosinophilic cytoplasm. Intranuclear inclusions are numerous**. The smear pattern is somewhat similar to that observed in papillary carcinomas of the breast with eosinophilic cytoplasm (see Chap. 29). The recognition of the tall-cell variant of papillary carcinoma of the thyroid is sometimes difficult (Jayaram, 2000; Filie et al, 1999; Ohori and Schoedel, 1999; Pisani et al, 1999; Bocklage et al, 1997; Cameselle-Teijeiro et al, 1997a; Gamboa-Dominguez et al, 1997).

Warthin's-Like Variant of Papillary Carcinoma

Originally described by Apel, Asa, and LiVolsi (1995), this form of papillary carcinoma is **morphologically indistinguishable from its salivary gland eponymic counterpart**. This tumor occurs primarily in women with Hashimoto's thyroiditis and behaves like other papillary carcinomas (Baloch and LiVolsi, 2000; Fadda et al, 1998). The aspiration combines cytologic features of **chronic thyroiditis and oxyphilic papillary carcinoma** (see Fig. 30-15) (Vasei et al, 1998; Yousef et al, 1997; Doria et al, 1996).

The cytologic recognition of this tumor type is difficult. On the one hand, the smear pattern is **reminiscent of Hashimoto's thyroiditis** but it may also mimic a **Hürthle cell tumor** because of marked cytoplasmic eosinophilia of tumor cells with nuclear cytoplasmic inclusions, forming **papillary clusters** (Fig. 30-20D). There is no uniformity of the tumor cells, some of which may resemble tall-cell variant and some the common type of papillary carcinoma.

Oxyphilic Variant of Papillary Carcinoma

This is an uncommon variant of thyroid cancer with low malignant potential that is sometimes classified as a papillary Hürthle cell tumor and sometimes as a variant of Warthin's-like papillary carcinoma (Vasei et al, 1998; Doria et al, 1996; Dzienciol et al, 1996). The cytologic findings are similar to those described for Warthin's-like carcinoma, except for the **absence of lymphocytes**.

P.1167

Tissue section of papillary carcinoma showing inspissated colloid. C. Metastatic papillary carcinoma of thyroid to the lung. Note the relatively large size of the tumor cells and the presence of a conspicuous intranuclear cytoplasmic inclusion with sharp edges. D. Biopsy of lung, corresponding to C, showing metastatic, papillary carcinoma. (A: MGG stain.)

Sclerosing Variant of Papillary Carcinoma

This tumor is seen more frequently in **children** and may be small but usually involves an entire lobe (Degnan et al, 1996). Some of these tumors may be **occult** and require ultrasound guidance for aspiration. The clinical and cytological findings do not match. The needle will encounter a **hard fibrous mass** but the aspirate, as in the Warthin's-like variant, will be composed of **lymphocytes and papillary clusters of cells**. The degree of cellularity is much greater than expected from a fibrous nodule (Yang et al, 1999; Kumarasinghe, 1998; Lugo-Vicente et al, 1998).

Medullary Carcinomas

The relatively uncommon medullary carcinomas of the thyroid are derived from **C cells** and produce **calcitonin**, a hormone regulating the metabolism of calcium and, hence, the skeleton. These tumors may also produce other polypeptide hormones, such as **somatostatin**, **bombesin**, and even **ACTH** that may cause Cushing's syndrome. The tumors may be sporadic or may occur as a **component of a familial multiple endocrine neoplasia (MEN)**, particularly the subgroups MEN2A and MEN2B, with synchronous tumors of other endocrine organs, such as a **pheochromocytoma** of the adrenal medulla and **parathyroid adenoma** (Forrest et al, 1998; Lips et al, 1994; Keiser et al, 1973).

In the familial form of medullary carcinoma, mutations of **RET protooncogene** are an important factor in the genesis of these tumors (recent summaries in Kebebew et al, 2000; Phay et al, 2000; Randolph and Maniar, 2000; see also Chap. 7). In patients who are carriers of MEN2 and familial medullary carcinoma gene, **prophylactic thyroidectomy** has been advocated. In a large study from France, all of the 71 patients at risk had either C-cell hyperplasia or medullary carcinoma (Niccoli-Sire et al, 1999). Many of such tumors are occult and, therefore, not likely to be diagnosed by preoperative biopsy (Krueger et al, 2000). Except for small tumors detected by screening, the **prognosis** of medullary carcinoma is poor (Cote and Gagel, 2003; Machens et al, 2003; Kebebew et al, 2000).

Histology

Medullary carcinomas may be single or multiple, the latter more common in patients with a genetic burden. The tumors are quintessential endocrine neoplasms with numerous **neuroendocrine granules** in the cell cytoplasm, a feature that is sometimes diagnostically very helpful. The principal

histologic feature of the tumor is the **association of epithelial tumor cells of various sizes and types with amyloid stroma**. In some tumors, the amount of amyloid may be substantial, reducing the volume of tumor cells. The tumors are richly vascularized.

P.1168

Figure 30-20 Variants of papillary carcinoma. A,B. High magnification showing follicular variant of papillary carcinoma stained with Diff-Quik (A) and with Pap stain (B). The only conspicuous abnormalities of note are the relatively large size of the nuclei, their ground-glass appearance, and occasional intranuclear cytoplasmic inclusions. C. Follicular variant of papillary carcinoma corresponding to B. D. Warthin's variant of papillary carcinoma stained with Diff-Quik. The smear shows Hürthle cells with conspicuous intranuclear cytoplasmic inclusions and scattered lymphocytes in the background.

The dominant histologic pattern is usually that of sheets or nests of **large, polygonal cancer cells**. However, a **carcinoid-like pattern of small cells** and **spindle cell pattern** are not uncommon. These patterns may occur side by side, accounting for a complex cytologic presentation of these tumors. The hormonal activity of these tumors, mainly **calcitonin**, may be documented by immunochemistry.

Cytology

The cytologic presentation in aspiration biopsies is fairly characteristic and corresponds to the diverse histological spectrum of cell types. The smears are usually cellular and the tumor cells are dispersed. Most often, the smears are composed of **large, epithelial cells** with abundant cytoplasm of irregular, but often of approximately **triangular shape** and large, hyperchromatic, **often eccentric nuclei, provided with prominent nucleoli** (Fig. 30-21A,B).

In some tumors, the cells closely resemble that of **plasma cells (plasmacytoid cells)**, except for their much larger size, a feature common to many endocrine tumors (Fig. 30-21C,D). In many tumors, the smears also contain scattered **giant cells with large, hyperchromatic nuclei** (Fig. 30-22C). This is a feature of many endocrine tumors that has no bearing on prognosis. **The cytoplasm of tumor cells is faintly granular** in fixed material, but may show **conspicuous red granules in air-dried May-Grünwald-Giemsa-stained smears** (Fig. 30-22), which are less distinct on Diff-Quik stains and cannot be seen in fixed smears. The granules reflect endocrine activity, most often **calcitonin secretion** by tumor cells that can be documented by electron microscopy in the form of endocrine cytoplasmic granules (see Fig. 2-20) or by immunocytochemistry (Fig. 30-22D).

Tumor variants composed wholly, or in part, of **spindly, elongated cells** (Fig. 30-23) or of **small cancer cells, resembling cells of a carcinoid** (Fig. 30-24A,B) must also be recognized. The small cell pattern may be **mistaken for a malignant lymphoma**, whereas the spindle cell tumors may be **mistaken for a sarcoma** or metastatic renal carcinoma (Koss et al, 1992). The various patterns may occur synchronously in the same smear (Kumar et al, 2000; Papaparaskeva et al, 2000; Green et al, 1997; Koss et al, 1992; Kini et al, 1984).

P.1169

Figure 30-21 Medullary carcinoma of thyroid. A-C. Various aspects of large cancer cells of diverse configuration. At high magnification, the cytoplasm is granular, particularly well shown in A (Diff-Quik stain) and C (MGG stain). In C and D, the cancer cells closely resemble plasma cells.

The amorphous substance, **amyloid** (which should not be confused with colloid), a characteristic component of medullary carcinomas of the thyroid, can be observed in fixed or Diff-Quik-stained, air-dried smears (Fig. 30-24A), as first reported by Ljungberg (1972). Congo red fluorescence confirms this diagnosis (Fig. 30-24D). Except for the very rare cases of **primary amyloidosis** involving the thyroid (Nijhawan et al, 1997), and equally rare **amyloid-producing thyroid plasmacytoma** (Bourtsos et al, 2000), **the presence of amyloid is diagnostic of medullary carcinoma, even if it is the sole finding** (Koss et al, 1992).

De Lima et al (2001) reported cytologic findings in a very uncommon **melanotic variant** of medullary carcinoma with pigmented tumor cells. Tseleni-Balafouta et al (1997) reported synchronous papillary and medullary carcinomas.

The cytologic recognition of medullary carcinoma and its metastases is very good (Forrest et al, 1998). Testing for serum **calcitonin levels** is often useful in confirming the diagnosis.

Anaplastic Carcinomas

Clinical Data and Histology

These highly malignant, frequently tender, rapidly growing tumors occur primarily in the elderly, usually appearing in the seventh decade of life (Carcangiu et al, 1985). At diagnosis, these tumors often have extensively infiltrated the thyroid gland and surrounding neck structures. They may, however, occur as a still localized nodule. Anaplastic carcinoma is the deadliest of all thyroid gland tumors, with few patients surviving 1 year after diagnosis.

There are **two forms of anaplastic carcinoma**: a **spindle and giant cell carcinoma** and a **small-cell-type carcinoma**. The question of appropriate classification of small-cell carcinomas has been repeatedly raised. It may be difficult to distinguish some of these tumors from an exceptionally aggressive malignant lymphoma, a small-cell medullary carcinoma, or a metastatic oat cell carcinoma (Uš-Krasovec et al, 1996).

Cytology

Smears of aspirates from **anaplastic giant cell carcinoma** usually contain **necrotic matter**, cellular debris, inflammatory cells, mainly granulocytes, and **large polymorphous, often multinucleated cells with large bizarre nuclei and very prominent nucleoli** (Fig. 30-24A-C). These tumors **should not be confused with the exceedingly rare carcinomas with giant cells, mimicking the giant cell tumors of bone** (see below) (Kumar et al, 1997; Koss et al, 1992; Berry et al, 1990).

P.1170

Figure 30-22 Medullary carcinoma of thyroid. A,B. Diff-Quik stains at high magnification show very large tumor cells with granular cytoplasm. C. High magnification of medullary carcinoma with giant cells. D. Cell block of medullary carcinoma with positive immunoperoxidase calcitonin stain, corresponding to C. (D: MGG.)

In **small-cell anaplastic carcinoma**, the aspirate contains malignant cells with **round or oval nuclei and scanty cytoplasm**. It must be noted that, even in tissue sections, small-cell anaplastic carcinoma may be difficult to distinguish from malignant lymphoma (Uš-Krasovec et al, 1996). Flow cytometric studies or immunocytochemical stains on the aspirate distinguish these two tumors.

Anaplastic carcinoma is considered, a priori, to be an **inoperable disease** and should be

treated aggressively with radiation and chemotherapy. Hence, diagnosis by FNA is critical in this disease. If the patient responds to radiation and chemotherapy, subsequent surgery may be considered.

Rare Malignant Tumors

Osteoclastoma Variant

This rare, highly malignant tumor mimics to perfection giant cell tumors of bone (Koss et al, 1992). The tumor contains **multinucleated giant cells with numerous small nuclei**, identical with osteoclasts and, in the background, sheets of small polygonal cells with similar nuclei. Cases of this tumor have been described and illustrated by Kumar (1997), Lee et al (1996), Koss et al (1992), and Williams et al (1979) (Fig. 30-25D).

This unusual tumor must be **distinguished from the anaplastic spindle and giant cell carcinoma**, characterized by very large, hyperchromatic, often bizarre nuclei of uneven sizes (see above).

Insular Carcinoma

This highly malignant tumor of the thyroid was first observed and described in Swiss patients with large goiters in the 1920s by Langhans as "Wuchernde Struma" or "proliferating goiter." The tumor, now very uncommon, has been renamed **insular carcinoma** (Rosai et al, 1985; Carcangiu et al, 1984) as a solidly growing tumor composed of medium-sized cancer cells separated by connective tissue septa into island-like compartments.

There is very limited information on the **cytologic presentation** of this tumor. Six cases were described by Guiter et al (1999) as **cellular smears with small spherical cancer cells** with poorly defined cytoplasm and monomorphic nuclei, occurring singly or in small clusters. The colloid was scanty and necrosis was present. Three of the six cases were initially thought to represent follicular neoplasms.

Squamous Carcinoma

Squamous carcinoma, primary in the thyroid, is vanishingly rare and must always be distinguished from metastatic

P.1171

tumors to the neck. Another potential source of error is the primary mucoepidermoid carcinoma (see below). The origin of primary thyroid squamous cancer may be in **squamous metaplasia** that may be occasionally observed in the lining of the thyroid cysts, in chronic thyroiditis, or thyroid adenomas. Squamous metaplasia may be quite exuberant and may mimic squamous carcinoma (Fig. 30-26A). The cells of squamous cancer are usually well differentiated and show the crisp, thick, eosinophilic cytoplasm characteristic of this tumor type (Fig. 30-26B).

Figure 30-23 Spindle cell variant of medullary thyroid carcinoma. A-C. Elongated cancer cells with large nuclei. D. The tumor corresponding to A. (B,C: Diff-Quik stain.)

A similar case with cytologic diagnosis was described by Kumar et al (1999). A case of **spindle cell squamous carcinoma and a synchronous papillary carcinoma**, tall cell type, was described by Saunders and Nayer (1999).

Mucoepidermoid Carcinoma

Primary mucoepidermoid carcinoma of the thyroid is a very rare disorder with uncertain prognosis occurring in patients of all ages. The origin of this tumor is not clear (Wenig et al, 1995).

There are **two variants** of the primary mucoepidermoid carcinoma of the thyroid. One variant is **similar in all aspects to mucoepidermoid tumors of the salivary glands** that include low- and high-grade tumors (Wenig et al, 1995) and the other, known as the **sclerosing variant**

with **eosinophilia**, is characterized by fibrosis and eosinophilic infiltration of the stroma (Baloch et al, 2000; Chan et al, 1991). Solomon et al (2000) pointed out that metastatic tumors of this type may **mimic Hodgkin's disease**.

The **cytologic presentation** of both types of mucoepidermoid carcinoma of the thyroid have been reported. The **common variant** is cytologically identical to lower high-grade tumors of the salivary glands (Vazquez Ramirez et al, 2000; Larson and Wick, 1993) (see Chap. 32). The smears contain squamous cells of various degrees of differentiation and with mucus-secreting cells or the presence of mucus.

The **sclerosing variant with eosinophilia** was reported as showing "deceptively bland tumor cells" (Bondeson and Bondeson, 1996) or, in a case with metastases, as a carcinoma with cytoplasmic eosinophilia (Geisinger et al, 1998). It is evident that because of the rarity of these tumors, no definitive cytologic criteria have been established. Mucoepidermoid carcinoma may also be associated with other tumor types, such as papillary carcinoma (Cameselle-Teijeiro et al, 1997b).

Malignant Lymphomas

Primary malignant lymphomas of thyroid, usually of B-cell derivation, may occur, particularly in patients with Hashimoto's

P.1172

thyroiditis (Singer, 1998). The cytologic presentation of these uncommon tumors may be complicated by the synchronous presence of epithelial components. Otherwise, the cytologic features of lymphomas are identical to those described for lymph nodes (Fig. 30-27; see Chap. 31). Immune typing of such aspirates is diagnostically helpful (Tani and Skoog, 1989). The majority of thyroid lymphomas arise primarily in the gland itself but may later involve lymph nodes and other organs, including the gastrointestinal tract and probably represents a form of mucosa-associated lymphoid tissue **MALT-related tumors** (see Chap. 31). Extension of extrathyroid lymphoma to the thyroid gland is uncommon (Matsuda et al, 1987). A case of signet-ring cell lymphoma of the thyroid was described by Allevato et al (1985). A case of T-cell lymphoma was described by Coltrera (1999).

Figure 30-24 Medullary carcinomas of thyroid. *A,B.* Small cell variant of medullary carcinoma. *A.* High-magnification view shows very small cancer cells with scanty cytoplasm and a fragment of amyloid stained with Congo red. *B.* Small cell medullary carcinoma of thyroid corresponding to *A.* *C.* Section of medullary carcinoma with abundant deposits of amyloid. *D.* Green fluorescence of amyloid stained with Congo red in a thyroid aspirate. (*D:* Courtesy of Prof. Stanislaw Woyke, Szczecin, Poland.)

Rare Benign Lesions

Two cases of **Langerhans' cell histiocytosis** of the thyroid were described by Behrens et al (2001) who also reviewed prior literature. The histology, cytologic presentation and clinical significance of this disorder are discussed in Chapters 20 and 31.

Courtesy of Dr. Berry Schumann, we have seen a case of **lipoma** of the thyroid, mimicking a thyroid tumor. The aspirate contained fragments of fat.

The Thyroid During Pregnancy and Postpartum

It is not uncommon for women to develop enlarged thyroids or thyroid nodularity during pregnancy or in the postpartum period. The **incidence of tumors** appears to be increased during this time (Marley and Oertel, 1997). At the same time, adenomatoid changes and benign papillary hyperplasia are rather common during pregnancy or lactation and most of these benign lesions regress after delivery. Consequently, **the diagnosis of follicular lesions of the thyroid in pregnancy or postpartum** must be made with great caution. Still, we observed several pregnant patients with a classical presentation of papillary carcinoma, recognized in

cytologic preparations. It is prudent to wait until after delivery for surgical removal of thyroid nodules.

P.1173

Anaplastic carcinoma of thyroid with osteoclast-like giant cells with multiple small nuclei. (*A,D*: Diff-Quik stain.)

Thyroid Aspiration in Children

Children not exposed to radiation do develop thyroid nodules that may be aspirated. The procedure is well tolerated. A large study of 57 patients ages 9 to 20 was reported by Khurana et al (1999). Nearly one-quarter of these young patients had malignant thyroid lesions, either **papillary** or **follicular carcinomas**, documenting the value of the procedure.

Figure 30-26 Squamous metaplasia and squamous carcinoma. *A* Shows squamous metaplasia occurring at the edge of a thyroid cyst. The lesion was benign. *B*. Aspiration biopsy of a thyroid mass showing typical cells of squamous carcinoma.

Metastatic Tumors

Metastases from cancers of the **kidney** (Fig. 30-28), **lung**, **breast**, **colon**, and **malignant melanomas** (Fig. 30-29),

P.1174

can cause clinically apparent thyroid lesions. The metastases to the thyroid occur either as single or multiple nodules or as a diffuse infiltration of the entire gland. Metastases may mimic primary tumors of the thyroid (Chen et al, 1999; Lam and Lo, 1998; Nakhjavani et al, 1997; Chacho et al, 1987; McCabe et al, 1985).

Figure 30-27 Malignant lymphoma of thyroid. *A*. Diff-Quik-stained smear showing typical appearance of malignant lymphoma of small cell type, confirmed by tissue biopsy

shown in *B*.

The cytologic diagnosis of a malignant tumor is usually easy. **The distinction between a metastasis and primary thyroid tumor may be difficult.** For example, **metastatic renal cell carcinoma** may be composed of **elongated, spindly cells** and thus **mimic a sarcoma or a medullary carcinoma** (Koss et al, 1992). Aspirates from metastases with **diffuse involvement of the thyroid** may yield groups or sheets of benign follicular cells intermingled with groups of obviously malignant cells displaying morphologic features not usually seen in primary tumors. This rare event may

P.1175

suggest a metastatic tumor, even in the absence of a known primary. In some cases, immunocytochemistry may be helpful in identifying tumor type (see Fig. 30-28).

Figure 30-28 Metastatic renal carcinoma to thyroid. *A,B.* Shows small cancer cells with vacuolated cytoplasm. The identity of the tumor could be determined by positive immunoperoxidase stains of cell block sections for keratin (*C*) and vimentin (*D*). (*A*: Diff-Quick. *B*: Papanicolaou stains.)

Figure 30-29 Metastatic melanoma to thyroid. Large tumor cells with bizarre nuclei and mitotic activity are shown. The melanin stains green in Diff-Quik stain (*A,B*) and brown in Papanicolaou stain (*C*).

Aspirates from large metastatic nodules usually contain only tumor cells and necrotic material. If the malignant cells display morphologic features uncharacteristic of the common primary tumors of the thyroid, such as **keratinization**, **mucin production**, **melanin production**, or **abundant clear cytoplasm**, a metastasis may be suggested. However, it should be noted that **very rare primary squamous cell and mucoepidermoid carcinomas** and **signet-ring cell thyroid tumors**, containing periodic acid-Schiff-positive material in their cytoplasm, have been described (Koss et al, 1992). Clinical-pathologic correlation and a history of a known outside primary tumor are critical in these cases.

REPORTING

The Papanicolaou Society of Cytopathology (Guidelines, 1996) has suggested guidelines for the examination and reporting of thyroid aspiration biopsies. These guidelines include the following terminology categories:

Adequate/inadequate

- Benign nonneoplastic lesions
- Cellular follicular lesion
- Hürthle cell neoplasm
- Malignant

The attempt to use this type of terminology is laudable and can be used in the laboratory, but we believe that the **reporting of FNA of the thyroid should attempt to match the histologic counterpart, should include the indications for surgical intervention and perhaps even include suggestions for medical therapy** or additional laboratory or imaging tests. For these reasons, the diagnostic report should expand beyond these five categories when possible.

Accuracy of Fine-Needle Aspiration of Thyroid

As has been stated in the opening pages of this chapter, the primary goal of thyroid aspirates is to **triage patients** with thyroid nodules into two groups: those who do require surgical removal and those who do not (Cap et al, 1999; Leonard and Melcher, 1997). The actual accuracy of diagnoses in terms of malignant versus benign is hampered by the follicular and Hürthle cell groups of tumors wherein it is nearly impossible to determine on cytologic, and sometimes histologic, grounds whether the lesion is benign or malignant. It is also of interest to determine whether the introduction of FNA improved the triage of patients. Such a study was performed at Montefiore Medical Center, comparing two periods, 1974 to 1977 before the introduction of FNA of the thyroid, and 1979 to 1981 after FNA of the thyroid was introduced (Koss et al, 1992). As shown in Table 30-2, although the total number

P.1176

of surgical excisions was reduced, the frequency of malignant tumors doubled, suggesting a much better triage of patients.

TABLE 30-2 EXPERIENCE WITH ASPIRATES OF THE THYROID AT MONTEFIORE MEDICAL CENTER			
Period of Study	Surgical Excisions of Thyroid	Incidence of Malignant Tumors	
		No.	%
1974-1977	141	22	16%
1979-1981	104	33	31%

To our knowledge, there is no similar study from other institutions. Today, the accuracy of the procedure is judged by comparing the results of thyroid FNA with histologic findings, thus calculating the sensitivity, specificity, negative, and positive predictive value. Numerous papers addressed this issue (Amrikachi et al, 2001; Baloch et al, 2000; Cap et al, 1999; Change et al, 1997; Davoudi et al, 1997; Boyd et al, 1992; Dwarakhanathan et al, 1985).

In general, the sensitivity of the procedure for benign and malignant lesions was in the range of 90% and the specificity about 80%. The negative predictive value was about 97%, whereas the positive predictive value was in the 40% range (Cap et al, 1999).

Other data on accuracy were provided by Davoudi et al (1997) who compared the results of FNA with frozen sections and by Carpi et al (1999) comparing aspirates with needle core biopsies. The diagnostic improvements with the frozen sections over FNA were trivial. Core needle biopsies (obtained with 18 gauge needles) were helpful in further triage of patients with preliminary diagnosis of "follicular neoplasm."

Of particular interest is the **performance of FNA in high-risk patients**. Hatipoglu et al (2000) discussed the finding in patients with prior irradiation of the head and neck lesions, Vriens et al (1999) in patients with familial nonmedullary thyroid cancer, and Forrest et al (1998) in patients with medullary carcinoma. The authors observed that in patients with multiple, small thyroid nodules the selection of the correct nodule is of critical importance. Liel (1999) observed that the functional status of the nodule (hot or cold) and the presence or absence of a goiter had no impact on the performance of the FNA. It appears that the principal goal of thyroid aspirates in **triage of common thyroid nodules** has been achieved in most institutions with adequate experience. This, among other things, has resulted in considerable cost savings as a result of the marked decrease in unnecessary surgery (Rimm et al, 1997; Maxwell et al, 1996). Segev et al (2003) addressed the issue of precise diagnosis of thyroid aspirates by means of **molecular markers** obtained by tissue **microarrays techniques**. Twelve promising markers were identified and may, in the future, assist in precise identification of "atypical" or "suspicious" aspirates.

The potential sources of error were discussed by Hall et al (1989) and Koss et al (1992) who

pointed out that inadequate skill of the operator is probably the most important cause of errors. Smears that are inadequate, diluted with blood, or simply miss the target, are a common event in inexperienced hands. Pressure on the pathologist to render an opinion on inadequate evidence contributes to interpretative errors.

PARATHYROID GLANDS

Anatomy and Histology

The four, or sometimes more, small, brown parathyroid glands measuring about 6 mm in diameter, are usually located at the posterior poles of the thyroid in the posterolateral part of the neck. The parathyroids are composed of sheets of **chief cells** with a pale or clear cytoplasm **secreting the parathormone** and **oxyphilic cells** with granular eosinophilic cytoplasm rich in mitochondria. In the adult, the normal parathyroid gland contains a great deal of fatty tissue. The **parathormone** regulates the metabolism of calcium and, hence, of the skeleton. **Enlargement or hyperplasia** of the parathyroids with increased secretion of the parathormone may lead to loss of calcium and skeletal disorders, known as the **brown tumors** or **osteitis fibrosa cystica**. Conversely, hyperplasia of the parathyroids may be the **consequence of chronic renal failure** with loss of calcium.

Parathyroid Adenomas

Clinical Data and Histology

Parathormone-secreting parathyroid adenomas remove calcium from the skeletal system with resulting serum **hypercalcemia**, loss of phosphate, and an increase in alkaline phosphatase. Besides the dangers to the skeleton deprived of calcium, hypercalcemia may result in **renal failure** caused by nephrocalcinosis. The tumors may occur sporadically or in patients with multiple endocrine neoplasia (MEN) type I (Marx et al, 1999). **Surgical removal** of the affected glands is the treatment of choice. Unfortunately, parathyroid adenomas are often quite small (1 cm in diameter, sometimes less) and are usually not palpable although, occasionally,

P.1177

larger tumors may occur (DeLellis, 1993). Sophisticated radiologic techniques are used to localize these tumors prior to surgery, which is quite often a hit-and-miss proposition. In recent years, a rapid **intraoperative parathyroid hormone assay** has been shown to be a secure guide to the surgeons attempting to remove parathyroid adenomas (Stratman et al, 2002; Westerdahl et al, 2002; Boggs et al, 1996; Irvin et al, 1991). A decrease in serum parathormone level by 50% or more, within 10 to 20 minutes after removal of single parathyroid adenomas, is very secure evidence that the source of parathormone has been removed. Persisting high levels are indicative of multigland disease, requiring further search. Parathormone assay is more accurate and sensitive than measuring total calcium levels in serum (Quiros et al, 2003). The role of the pathologist is to determine whether the small piece of tissue represents a parathyroid adenoma or other tissue, such as the thyroid.

Parathyroid adenomas are composed mainly of **chief cells** and **cells with water-clear cytoplasm**. Oxyphilic adenomas are rare. Although most adenomas are located posteriorly to the thyroid gland, about 10% are ectopic in various locations, such as the mediastinum or posterior esophagus (DeLellis, 1993). The adenomas may undergo **infarction**, hemorrhage, or **cystic degeneration**. The role of cytopathology is to assist the surgeon in identifying parathyroid adenomas, either as an intraoperative consultation or, in some cases, by preoperative thin needle aspiration of palpable lesions or lesions localized by ultrasound.

Cytology

On **touch preparations**, the cells of parathyroid adenomas or hyperplasia are similar: the cells occur in clusters that are usually tightly knit. The cytoplasm is eosinophilic and clear and the nuclei small (Fig. 30-30). There are **two features** of these smears that separate the parathyroid cells from follicular cells of the thyroid: **absence of colloid** and, in fortuitous cluster, **more abundant eosinophilic or clear cytoplasm** with formation of typical **honeycomb pattern**. In FNA, large sheets or flat clusters of epithelial cells, **sometimes with a central capillary**, may be observed (Kini et al, 1993).

Figure 30-30 Hyperplastic parathyroid. The parathyroid cells show spherical nuclei of equal sizes and abundant eosinophile cytoplasm. Note the spherical red blood cells on

right. (Diff-Quik stain.)

The most significant problem with cytology of the parathyroid is its **similarity to the thyroid**.

There are several reports in the literature stressing this point (Halbauer et al, 1991; Mincione et al, 1986; Davey et al, 1984; Friedman et al, 1983; Guazzi et al, 1982). The few reports of **cystic parathyroid adenomas** also report confusion with cystic thyroid lesions in most cases (Lerud et al, 1996; Layfield, 1991). Auger et al (1999) reported a case of parathyroid adenoma mimicking Hashimoto's thyroiditis. Bondeson et al (1997), with a colossal experience with 1,600 such aspirates, stated that there is **no single morphologic feature** that can securely identify the parathyroid origin of cells and the material must be evaluated by clinical, biochemical and immunocytologic data. Galloway et al (1996) reported cytologic diagnoses of an **ectopic parathyroid adenoma** in supraclavicular location.

In fact, the only feature that confirms the presence of parathyroid cells is cytochemistry. Thus, Halbauer et al (1991) used **Grimelius silver stain to identify secretory granules**, resulting in successful identification of parathyroid lesions in slightly more than half of 146 patients. A still more secure identification is provided by **immunostaining for parathyroid hormone** (Bondeson et al, 1997; Winkler et al, 1987; Silverman et al, 1986). We had a similar experience in parathyroid carcinoma (see below). In cystic lesions, the presence of parathormone in fluid may be established by radioimmunoassays (Lerud et al, 1996).

Parathyroid Carcinomas

These tumors are extremely rare and, in most cases, do not differ morphologically from parathyroid adenoma and are often classified as **parathyroid hyperplasia** (Case Records Massachusetts General Hospital No. 7-2002; Shane, 2001; LiVolsi, 1994; DeLellis, 1993). Yet, these tumors are capable of invasive behavior and metastases. A case in point is shown in Figure 30-31. The patient was a 33-year-old woman with a large mass involving the right lobe of the thyroid, considered clinically to be a thyroid neoplasm. The mass was considered "cold" on scintigraphy. A needle aspirate was interpreted as showing follicular cells, consistent with a follicular neoplasm.

P.1178

On review of the smears, it was noted that the cell clusters were unusually complex (Fig. 30-31A) and some of the nuclei were somewhat hyperchromatic (Fig. 30-31B) yet, even with the full knowledge of the final outcome, the diagnosis of parathyroid adenoma, let alone carcinoma, could not be established. Surgical resection revealed a well-differentiated parathyroid neoplasm infiltrating the adjacent soft tissues (Fig. 30-31C). The parathormone stain was positive (Fig. 30-31D). Not surprisingly, the reported FNA cases of parathyroid carcinoma failed to document persuasive malignant features in cells of these tumors (Hara et al, 1998; Guazzi et al, 1982; Garza et al, 1985). Of interest is a recent report indicating a high incidence of **HRPT2 mutations** in patients with parathyroid carcinomas (Shattuck et al, 2003). The HRPT2 gene encodes the parafibromin protein, but the mechanism of action of this protein in cell physiology and tumor suppression are unknown.

Figure 30-31 Parathyroid carcinoma in a 33-year-old woman. *A,B.* Aspiration of what was thought to be a thyroid nodule. In *A*, the complexity of the cell clusters is evident. In *B*, the nuclei are somewhat hyperchromatic and surrounded by ample clear cytoplasm. This smear was interpreted as showing a follicular tumor of the thyroid. *C.* Histologic section of tumor that was infiltrating the adjacent thyroid, with positive immunoperoxidase stain for parathormone shown in *D*.

OTHER NECK MASSES, EXCEPT LYMPH NODES

Besides lymph nodes, which are discussed in Chapter 31, other masses in the neck may be amenable to FNA. The most common lesions are **lipomas, thyroglossal ducts cysts, branchial cleft cysts, and tumors of the carotid body**. Tumors of soft parts may also involve

the neck (see Chap. 35).

Lipoma

Fine needle aspiration of a **lipoma** yields pure mature, benign fatty tissue, usually occurring as clumps of overlapping large cells with clear, vacuolated cytoplasm. One must be sure, as in all FNAs, that the needle sampled the actual tumor mass and not the surrounding normal fatty tissue before concluding that the lesion is a lipoma. Lipomas, as discussed in Chapter 35, can occur just about anywhere in the body.

Thyroglossal Duct Cysts

Thyroglossal duct cysts are the result of a cystic dilatation of the thyroglossal duct. Embryologically, the thyroglossal duct is formed in the course of the development and descent of the thyroid gland from the foramen cecum in the tongue to its normal location in front of the trachea. Normally, the thyroglossal duct disappears. However, it may persist and

P.1179

may become cystic, probably as a result of secretion from the mucosal lining cells. The normal location of a thyroglossal duct cyst is the **midline of the anterior neck, in the region of the hyoid bone. The cysts are lined by columnar or squamous epithelium and may contain thyroid tissue in their walls** (Fig. 30-32). On very rare occasions, a **papillary thyroid carcinoma** may arise within a thyroglossal duct cyst.

Fine needle **aspiration** of a benign thyroglossal duct cyst usually yields **colloid material**, sometimes containing a **few mature squamous or columnar epithelial cells**. In order to correctly interpret the material present in the smear, one has to know the precise location of the mass because, by cytology alone, it may be difficult to differentiate thyroglossal duct cyst from a colloid goiter.

Branchial Cleft Cysts

Branchial cleft cysts are congenital cysts that are located in the lateral aspect of the neck. They are the result of developmental anomalies of the branchial clefts. Apel et al (1994) reported branchial cleft cysts located within the thyroid. The cysts may remain occult until middle or older age and may appear suddenly. The branchial cysts may become inflamed and clinically painful. The cysts are usually **lined by mature squamous epithelium supported by a stroma rich in lymphoid tissue, sometimes forming mature lymph follicles**. Occasionally, the squamous epithelium is less mature and is composed of smaller squamous cells of parabasal type with large nuclei (Fig. 30-33). On rare occasions, part of the cyst lining will be composed of **mucus-producing columnar cells**.

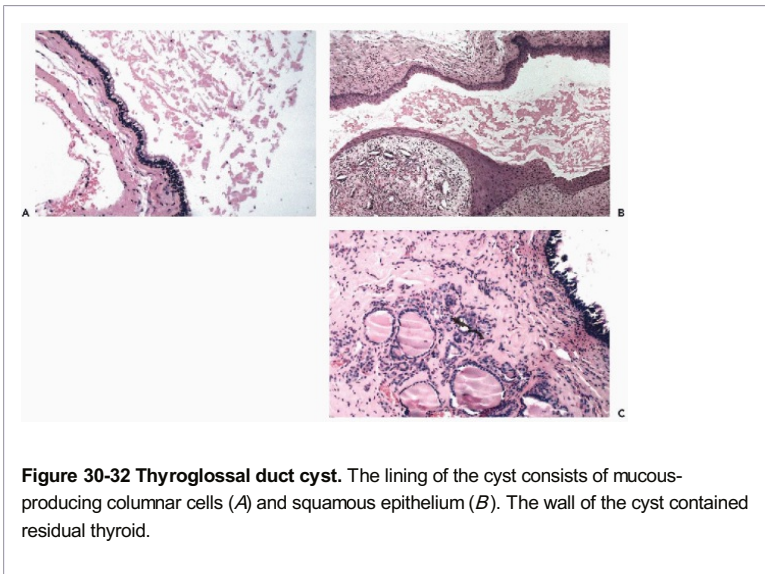

Figure 30-32 Thyroglossal duct cyst. The lining of the cyst consists of mucous-producing columnar cells (A) and squamous epithelium (B). The wall of the cyst contained residual thyroid.

Cytology

Aspiration usually yields thick, very **turbid, white** or **yellow fluid**. The cysts may disappear after complete aspiration of the contents, resulting in cure. However, some cysts may recur and the fluid can reaccumulate.

Microscopically, the fluid contains a variable number of **mature squamous cells and acellular squames**, proteinaceous material, cellular debris, and lymphocytes. Less often, and particularly in the presence of inflammation, the **squamous cells** may be smaller, of a parabasal or even basal type, and may show **nuclear enlargement, some hyperchromasia**, or even pyknosis (Fig. 30-33A,B). The smear **background** may show evidence of acute or subacute **inflammation** and sometimes may contain **granulation tissue**, characterized by **numerous capillaries, fibroblasts, and mono- and multinucleated macrophages** (Koss et

al, 1992).

Branchial cleft cysts must be differentiated from **metastatic squamous cell carcinoma**, especially the well-differentiated, keratin-forming type that may become cystic (Fig. 30-33C,D).

The degree of cellular atypia in a branchial cleft cyst may mimic carcinoma, and conversely, the cells of squamous carcinoma may be so well-differentiated that they may mimic a branchial cleft cyst. Usually, but not always, the cells of squamous cell carcinomas show more significant nuclear atypia. Clinical history is often helpful but neck metastases of squamous carcinoma may occur in the absence of a known primary. Obviously, any doubts as to the diagnosis should lead to a recommendation for an excisional biopsy.

P.1180

Figure 30-33 Branchial cleft cyst and well-differentiated squamous carcinoma. *A,B.* Branchial cleft cyst. The smear contained numerous morphologically normal squamous cells (shown in *A*), corresponding to the lining of the branchial cleft cyst shown in *B*. *C,D.* Metastatic well-differentiated squamous carcinoma mimicking a branchial cleft cyst. *C.* The tumor cells show only minimal deviation from normal and should be compared with those shown in *A*. *D.* Well-differentiated squamous carcinoma in a neck lymph node corresponding to *C*.

Figure 30-34 Carotid body tumor: direct aspirate. *A.* The smear shows cells at high magnification with granular, eosinophilic cytoplasm, mainly dispersed, but also forming a small, approximately spherical cluster. Note the variable size of nuclei, some of which are very large. *B.* The tissue section of the tumor shows nests of cells surrounded by connective tissue. (Photographs courtesy of Dr. M. Zaman, New York Medical College, Valhalla, NY.)

P.1181

Carotid Body Tumors

The **rare carotid body tumors** belong to the family of paragangliomas and, for the most part, occur as a **painless mass in the lateral aspect of the neck**. The tumors are usually located at the bifurcation of the common carotid artery and are adherent to it. On palpation, the tumors may be pulsating, and a bruit may be heard on auscultation. The tumors are usually benign but, in about 10% of cases, are capable of metastases that sometimes may occur many years after removal of the primary.

The tumors are richly vascularized and are composed of nests of **large polyhedral cells with granular cytoplasm, often with significant nuclear atypia** (Figs. 30-34B and 30-35C,D). It should be stressed that in this, as in many other endocrine tumors, **cellular and nuclear pleomorphism should not be taken as evidence of malignancy**. The aspiration of a carotid body tumor may be **dangerous to the patient**, who may react with syncope caused by a sudden increase in blood pressure, resulting from secretion of norepinephrine. Therefore, **if the diagnosis can be established on clinical grounds, an aspiration should be avoided**.

As a result, there are only a few reports on aspiration cytology of carotid body tumors (Linsk and Franzén, 1989).

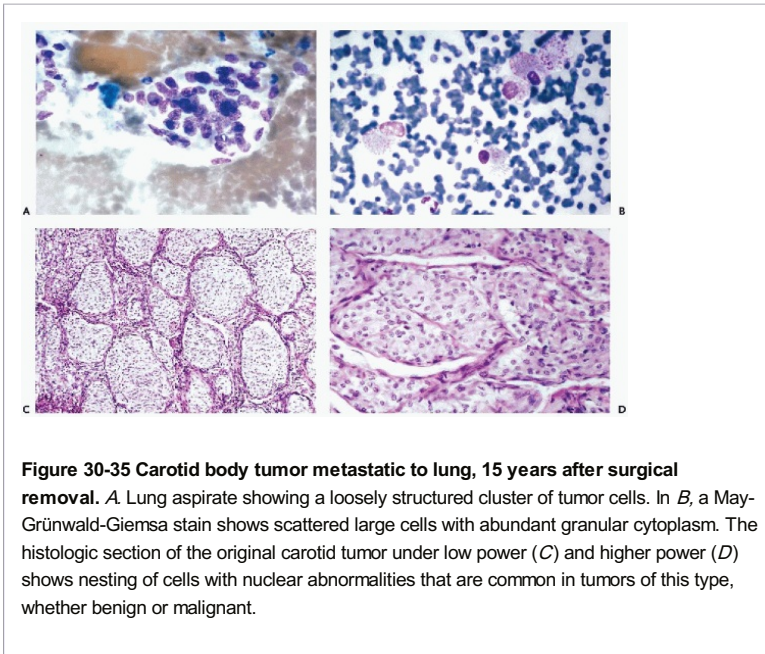

Figure 30-35 Carotid body tumor metastatic to lung, 15 years after surgical removal. A. Lung aspirate showing a loosely structured cluster of tumor cells. In B, a May-Grünwald-Giemsa stain shows scattered large cells with abundant granular cytoplasm. The histologic section of the original carotid tumor under low power (C) and higher power (D) shows nesting of cells with nuclear abnormalities that are common in tumors of this type, whether benign or malignant.

Cytology

Descriptions of the cytology of these tumors may be found in Linsk and Franzén (1989), Hood et al (1983), and Engzell et al (1971). The smears contain blood and **tumor cells, which are either isolated, in loosely arranged groups, or form rosettes**. The cells are often large, polygonal, ovoid, or elongated. The abundant cytoplasm is granular or dense, may be eosinophilic on hematoxylin and eosin stain, and is pale on Papanicolaou stain. **Red cytoplasmic granules** may be seen in the Giemsa stain. Centrally or eccentrically located **nuclei show considerable variation in size and shape**. **Giant nuclei** and multinucleated giant cells may occur but have no bearing on the malignant nature of the tumor. The chromatin is finely or coarsely granular and conspicuous nucleoli may be seen (Fig. 30-34A). The cytologic features of carotid body tumors may **mimic metastatic**

P.1182

carcinoma, especially when a tumor is thought to be an enlarged lymph node. The presence of rosette-like structures may be suggestive of a follicular tumor of the thyroid gland. However, **a carotid body tumor will not move on swallowing, whereas a thyroid tumor will**. As in all FNA interpretations, **clinical-pathological correlation is of paramount importance**. The material is easiest to interpret when the aspiration is performed by the person reading the smears.

Koss et al (1992) reported a case of metastatic carotid body tumor to the lung occurring 15 years after removal of the primary tumor (Fig. 30-35).

Other Rare Findings

A case of cytologic recognition in FNA of **ectopic thymic tissue** in the neck of an infant was described by Tunkel et al (2001). **Epidermoid inclusion cysts** may also occur. Pavot et al (2001) described such a case with **Liesegang rings** in the aspirated fluid (see Chap. 25 for description).

Other lesions of note are **fibromatosis** of the neck and tumors of muscle and soft tissues, not specific to the neck, described in Chapter 35.

Extracranial meningiomas are usually observed in newborns as tumors of the head and neck area (Lopez et al, 1974). For description of cytology of meningiomas, see Chapter 42.

Lymph Nodes

Nancy P. Caraway

Ruth L. Katz

Needle aspiration of lymph nodes is one of the oldest applications of the technique in the diagnosis of human disease. In 1904, two British military surgeons, Greig and Gray, working in Uganda, published a paper describing the diagnosis of sleeping sickness by recognizing mobile trypanosomes in lymph node aspirates. In 1921, Guthrie of Johns Hopkins described the application of needle aspiration to the diagnosis of tumors. In 1930, Martin and Ellis of Memorial Hospital for Cancer (now the Memorial Sloan-Kettering Cancer Center) included tumors that had metastasized to the lymph nodes among the targets of aspiration biopsy.

As a result of the pioneering work of Franzén et al (1960) and the widespread current acceptance of the technique, aspiration of lymph nodes has become a standard laboratory procedure.

The spectrum of applications of fine needle aspiration (FNA) biopsy in diagnosing disease has become ever wider. Although metastatic cancer is still the most common target of lymph node aspiration, a large number of benign disorders have been identified using the procedure. Applications of immunologic techniques now allow a secure identification of a broad spectrum of primary malignant lymphomas.

ANATOMY AND HISTOLOGY OF LYMPH NODES

A lymph node may be conceived of as an encapsulated spongy sieve, filtering and modifying the lymphatic fluid between the points of entry and exit. The normal lymph node is bean-shaped, with lymph entering the node through the afferent lymphatics, piercing the convex surface of the capsule, and exiting through the efferent lymphatics in the hilus, which is an area of indentation in the concave side of the node. The principal component of the lymph node is lymphoid tissue, which is normally distributed in an orderly fashion within compartments that are constructed of connective tissue and circulatory sinuses (Fig. 31-1).

A connective tissue capsule encloses the lymph node, which is further subdivided into anatomic compartments by a number of connective tissue trabeculae that extend from the convex aspect of the capsule to the hilus. The

P.1187

capsule and the trabeculae provide the framework for a series of circulatory channels or sinuses, which are lined by endothelial cells and are filled with lymph fluid and the cells carried within it.

Figure 31-1 Diagrammatic presentation of lymph node structure.

The following brief overview of lymphocyte classification is cited merely in support of the anatomic data. **There are two principal families of lymphocytes, the thymus-derived (T) and bursa- or bone marrow-derived (B) lymphocytes.** Although the significance of this classification is not discussed at length here, **a principal function of the B lymphocytes and derivative cells, such as plasma cells, is the formation of immunoglobulins, which confer humoral immunity, whereas T lymphocytes play a major role in cell-mediated immunity.** Complex interactions are now known to exist between the B and T lymphocytes and their subsets. Lymphocytes without obvious B or T characteristics have been designated, in the past, as **null cells**. With the use of additional markers, these cells can now be classified as either B or T or their subtypes. Classes of **dendritic follicular cells** that may interact with lymphocytes by processing antigens are also present in lymph nodes; they populate sinusoidal, stromal, and T and B areas.

The **distribution of the B and T cells** in a normal lymph node is orderly and follows anatomic divisions. Three regions of the lymph node can be distinguished: **the cortex**, which is situated beneath the capsule; **the medulla**, which is close to the hilus; and **the intermediate paracortex**, which is located between the capsule and hilus. The cortex and medulla represent zones of B cells, whereas the paracortex represents a zone of T cells.

The cortex contains the majority of lymphatic nodules (follicles) which, during postnatal life, usually contain germinal centers. **As a consequence of antigenic stimulation, the small B-lymphocytes within the germinal centers are transformed into large cells that have large, round nuclei and prominent nucleoli.** Previously known as reticulum cells, these large cells have been designated by Lukes and Collins (1974) as **large noncleaved cells** and by Lennert (1967) as **centroblasts**. The transformation of the small lymphocytes into the large noncleaved cells proceeds through several stages and forms, identified by Lukes and Collins (1974) as **small cleaved cells, large cleaved cells, and small noncleaved cells**. The large noncleaved cells may participate in further lymphopoiesis or transform into **immunoblasts** which, outside of the germinal centers, evolve into plasma cells. Cumulatively, the transformed lymphocytes may be designated as **follicle center cells**. The germinal centers also harbor

macrophages that usually contain fragments of phagocytized material in their cytoplasm (**tingible body macrophages**), and the nonphagocytic **dendritic reticulum cells** that have pale vesicular nuclei, tiny nucleoli, and abundant, ill-defined cytoplasm.

The **paracortex** contains small T-type lymphocytes that are suspended in nests composed of interdigitating reticulum cells. Under antigenic stimulation, the T-type lymphocytes may evolve into T-type immunoblasts.

The **medulla** is composed of small B-type lymphocytes that are packed tightly in sheets and cords separated by medullary sinuses. The lymph nodes also contain cells previously known as **null cells** that do not appear to be assigned to any specific anatomic compartment but are either of B or T derivation. Dendritic cells are dispersed among the various elements of the lymph node and are active in presenting antigens to the lymphocytes. These cells have cytoplasmic extensions ("dendrites") and may express keratin.

Immunologic techniques, described in this chapter and in Chapter 45, are required to identify the different types of lymphocytes because they cannot be distinguished from each other by light microscopic features, either in histologic sections or in cytologic smears.

Normal children and young adults have well-developed lymph nodes with numerous follicles. A reduction in the number of lymph follicles is common in the elderly. A regression of lymphoid tissue may also be observed, with replacement either by fat, for example, in the axillary lymph nodes, or by connective tissue, as observed in the inguinal lymph nodes.

FINE-NEEDLE ASPIRATION BIOPSY TECHNIQUE

Aspiration biopsy should be limited to enlarged lymph nodes that are either superficial and palpable or deep and visualized using a radiologic or ultrasound technique. The aspiration of palpable lymph nodes should be performed by a person familiar with the principles of this technique, discussed in Chapter 28. After cleansing of the skin, palpable lymph nodes should be immobilized between the fingers of one hand before the aspiration is performed with the dominant hand. Otherwise, the tip of the needle may displace the target, resulting in an inadequate specimen.

For routine aspirations, air-dried, methanol-fixed smears stained with a variant of the Romanovsky hematologic stain (May-Grünwald-Giemsa or Diff-Quik) and alcohol-fixed smears stained with Papanicolaou should be made.

Preliminary Assessment of Smears

The first task in evaluating a smear from a patient with lymphadenopathy is to assess its compositions and cellular

P.1188

features. The cell population may be polymorphous, containing a mixture of cell types, or monomorphous, containing one predominant cell type. A schematic outlines the differential diagnosis of polymorphous (Fig. 31-2) and monomorphous (Fig. 31-3) populations.

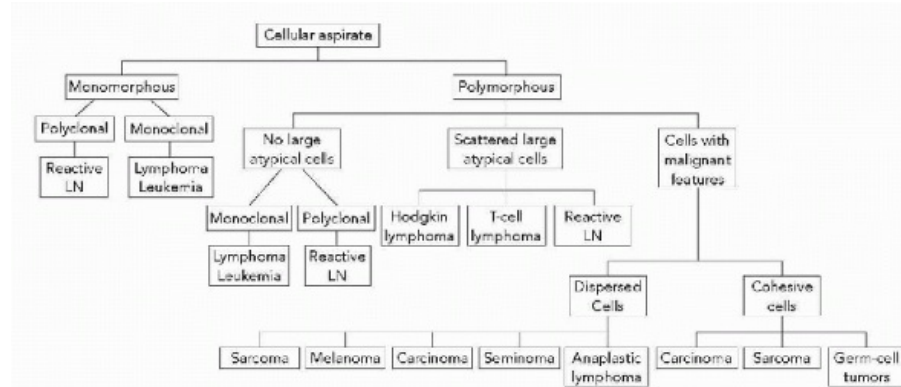

Figure 31-2 Assessment of cells in lymph node (LN) aspirate.

An important index of the presence of lymphocytes in smears is the presence of **lymphoglandular bodies**, first observed by Downey and Weidenreich (1912) and subsequently recognized as an important diagnostic landmark by Söderström in his book published in 1966. **The lymphoglandular bodies (also known as Söderström bodies) are approximately spherical, small, pale, basophilic fragments of cytoplasm that are best observed against the background of air-dried, MGG-stained smears of lymph nodes or bone marrow** (Khoory, 1983; Flanders et al, 1993; Francis et al, 1994). The importance of lymphoglandular bodies in the diagnosis of malignant lymphoma is described in the next section.

Further Evaluation of Samples

Depending on the results of the initial cytologic evaluation and the clinical history, appropriate ancillary studies can be performed (Fig. 31-4). An adequate portion of the aspirate should always be saved in tissue culture medium or another transport medium. It is helpful to count the saved cells to determine whether the sample is adequate for ancillary studies. If an infectious process is suspected, then material should be obtained for microbiologic culture and special stains for microorganisms (e.g., Gomori's methenamine silver, Ziehl-Neelsen, Gram stains).

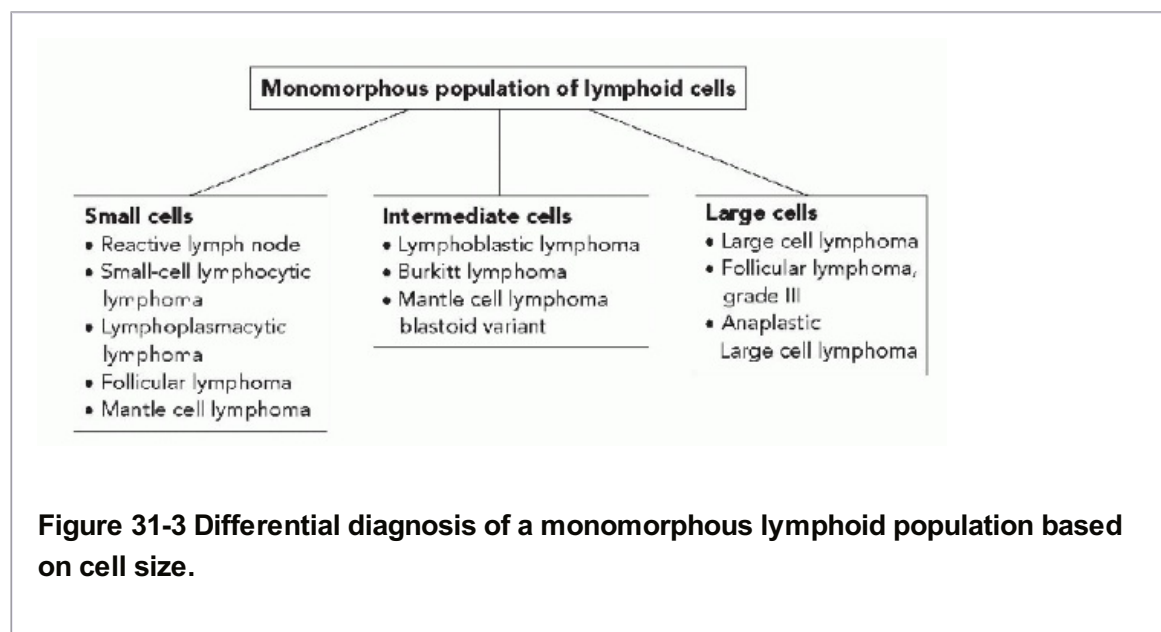

Figure 31-3 Differential diagnosis of a monomorphous lymphoid population based on cell size.

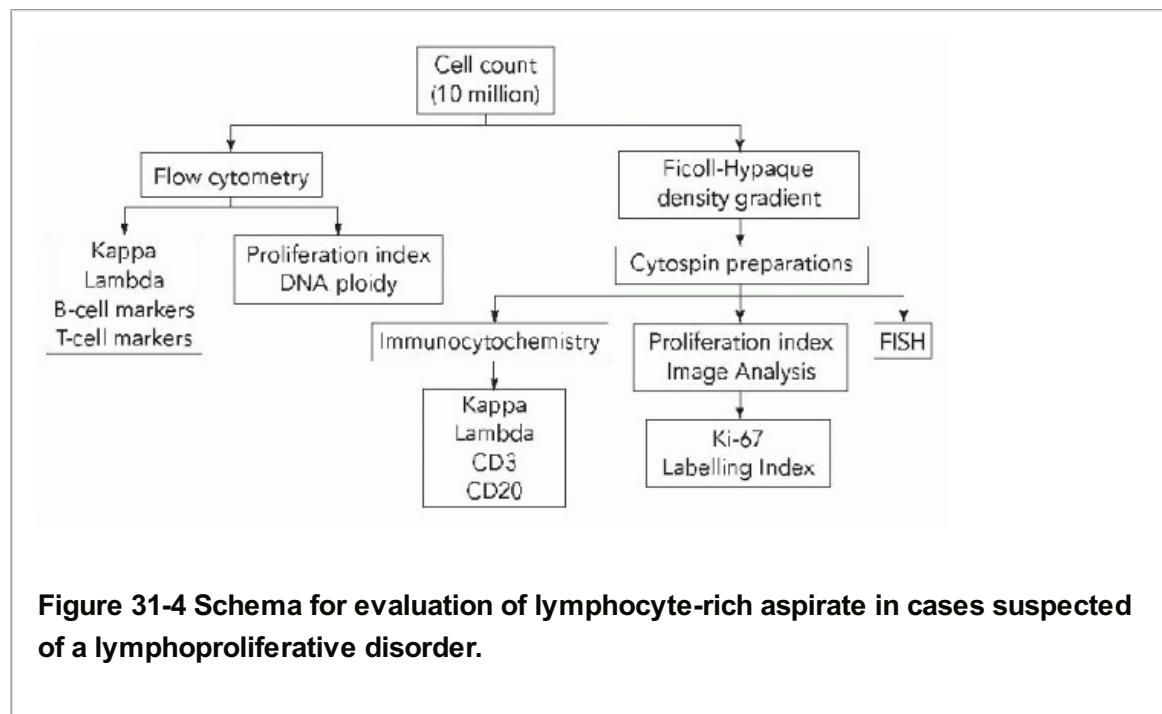

Our approach to the work-up of **suspected lymphoproliferative disorders** consists of the following steps:

- **Immunophenotyping** is performed with flow cytometry or immunocytochemistry on cytospin preparations (Sneige et al, 1990; Katz et al, 1993a). In the initial workup of a lymphoproliferative disorder, an **optimal flow cytometry panel** includes antibodies to kappa, lambda, CD3, CD5, CD10, CD19, CD20, and CD23 antigens, coexpression of CD19 and CD5, and coexpression of CD19 and CD10. For explanation of the significance of these antibodies see Chapters 5, 47, and the discussion of lymphomas below. This panel is useful in classifying most of the lymphomas and can be modified depending on the differential diagnosis (Fig. 31-5). A **limited panel** consisting of kappa and lambda to determine clonality,

P.1189

a T-cell marker (CD3), and a proliferation marker (Ki-67) can be performed if the patient has a previous diagnosis of lymphoma and the cytomorphologic features correlate with that diagnosis.

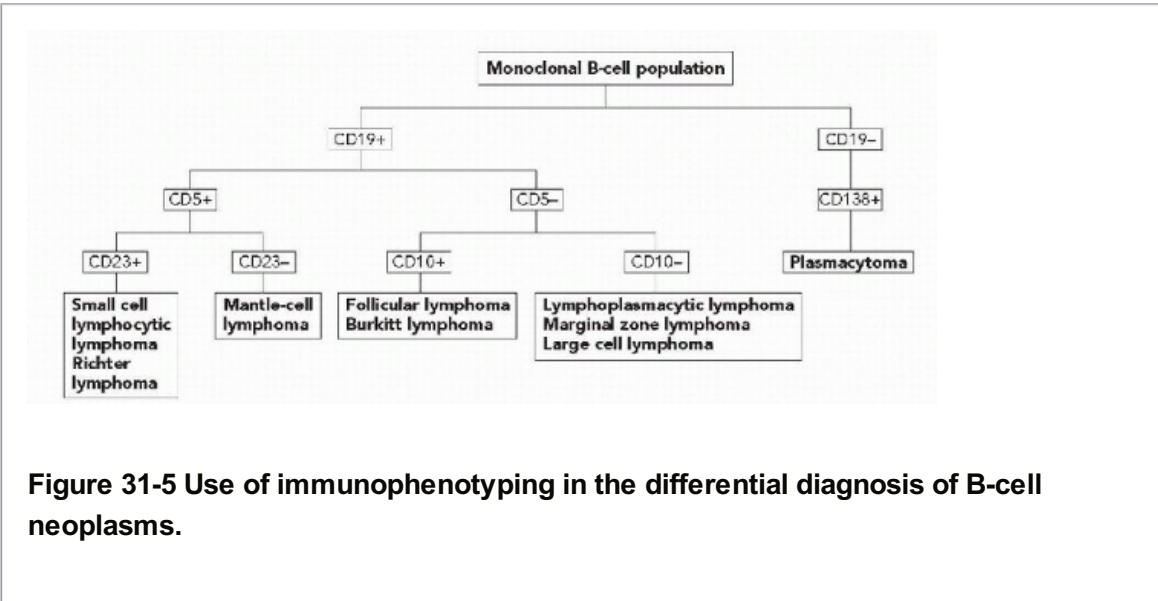

- **DNA ploidy analysis** is used to analyze the proportion of cycling cells by image analysis, flow cytometry, or immunostaining with Ki-67 (Katz et al, 1993b; 1993c).
- **Conventional cytogenetic testing or fluorescence in situ hybridization (FISH)** is used to confirm lymphomas characterized by particular reciprocal chromosomal abnormalities (Caraway et al, 1999; Katz et al, 2000; Thorson et al, 2000; Najfeld, 2003).
- **Genotyping** is performed only in the rare cases of nonmarking lymphomas, low-grade T-cell lymphomas, lymph nodes partially involved by lymphoma, or equivocal marker studies (Katz et al, 1991).

NONNEOPLASTIC LYMPH NODES

The principal indication for FNA is persistent enlargement of lymph nodes, and the purpose of the procedure is to establish causes of lymphadenopathy that cannot be reliably diagnosed on clinical grounds (Table 31-1). Such nonneoplastic conditions as inflammation, infection, autoimmune disorders, and hypersensitivity reactions are associated with lymphadenopathy

(Dorfman and Warnke, 1974; Koss et al, 1992).

Acute Lymphadenitis

Clinically, acute lymphadenitis usually appears as a red, hot, tender area. Superficial lymph nodes that drain a dental abscess, an inflamed appendix, a tubo-ovarian abscess, or an infected wound are typically affected. The most common causes of acute lymphadenitis are bacteria or their toxic products.

Early in the disease process, lymph node aspirates contain an admixture of neutrophils and lymphocytes. Later, the aspirates contain a purulent material composed of neutrophils and cellular debris (Fig. 31-6). As the acute inflammatory process subsides, neutrophils are admixed with plasma cells and large macrophages containing fragments of phagocytized material, known as **tingible body macrophages**. The aspirated material can be sent for bacterial culture. Although Gram staining can be performed on aspirates, the results may be difficult to interpret, especially on smears that are destained and restained.

Chronic Lymphadenitis (Reactive Hyperplasia)

Chronic lymphadenitis, more often referred to as reactive hyperplasia of lymph nodes, is the most common cause of lymphadenopathy and the most common diagnosis made on lymph node aspirates.

Lymph node enlargement in chronic conditions may be caused by an enlargement of the lymphoid follicles, the pulp of the lymph nodes, the peripheral sinuses, or a combination of all three. In reactive hyperplasia, one component of the lymph node usually predominates and, therefore, the disorder is usually classified by pattern (Table 31-2). However, the architectural pattern cannot be assessed by FNA and, therefore, it is difficult to determine specific causes of benign hyperplasia in a cell sample.

Follicular and Paracortical Hyperplasia

Follicular hyperplasia can occur at any age, but it is more common in children. The cervical, axillary, and inguinal lymph nodes are frequently involved because they drain large areas of the body. Reactive nodes are usually less than 3 cm in diameter, although they may be larger in children.

Figure 31-6 Suppurative lymphadenitis. Aspirate shows acute inflammatory cells and cellular debris.

Cytology

In general, the aspirates are quite cellular and are composed of dispersed, isolated, single cells with marked variability in size and configuration. Small lymphocytes are usually the dominant cell type (Fig. 31-7). Follicle center cells, which are a mixture of small and large lymphocytes with cleaved nuclei, large cells with vesicular nuclei, and immunoblasts, are present in varying proportions, sometimes forming small cell aggregates (Fig. 31-8). In optimal preparations, one may be able to differentiate between **large noncleaved cells** (centroblast) containing two or three nucleoli located near the nuclear membrane and **immunoblasts** containing only one centrally placed, often irregular, large nucleolus (Koss et al, 1992). Plasma cells and tingible body macrophages are usually present, the latter recognized by their very large size and the presence of phagocytized debris in their vacuolated cytoplasm (Fig. 31-9). Dense, basophilic fragments of apoptotic nuclei and occasional mitotic figures may be seen.

Immunophenotyping reveals a typical polyclonal population with no clonal excess of light chains (Fig. 31-10). Reactive T cells may constitute a large proportion of the cell population; however, if they exceed 80%, a low-grade T-cell lymphoma should be considered. DNA ploidy analysis usually shows **a diploid population with variable S-phase**.

Conditions Associated with Follicular and Paracortical Hyperplasia

Rheumatoid arthritis is an autoimmune disease that is associated with lymphadenopathy. In rheumatoid arthritis, aspirates show florid, reactive hyperplasia and numerous plasma cells with eosinophilic, cytoplasmic inclusions, known as **Russell bodies**. Similar changes can be seen in lymph nodes from patients with Sjögren syndrome, characterized by keratoconjunctivitis and xerostomia, and Felty syndrome, characterized by splenomegaly, hematologic disorders that result from hypersplenism, leg ulcers, and polyarticular rheumatoid arthritis.

Systemic lupus erythematosus (SLE) is also associated

P.1191

with lymphadenopathy. Aspirates taken from patients with SLE show numerous small lymphocytes, transformed lymphocytes, and tingible body macrophages in a background of necrosis. In addition, LE cells in various stages of formation may be observed. The LE cells contain amorphous basophilic bodies, composed of aggregates of DNA, polysaccharides, and immunoglobulins, and ranging from 5 to 12 microns in diameter (Ko and Lee, 1992; see Chap. 26).

TABLE 31-2 CONDITIONS ASSOCIATED WITH REACTIVE LYMPHOID HYPERPLASIA: PREDOMINANT HISTOLOGIC PATTERN BY ETIOLOGY

Figure 31-7 Reactive lymph node. Smears show predominantly small cleaved lymphocytes and occasional noncleaved cells.

Castleman disease is also known as giant lymph node or angiofollicular hyperplasia. There are two morphologic subtypes: the more common **hyaline-vascular** and the less common **plasma cell variant**. The hyaline-vascular type

P.1192

can affect patients of any age, but most are asymptomatic young adults. The mediastinum is most commonly involved, followed by the cervical lymph nodes. Aspirates taken from patients with the hyaline-vascular form of **Castleman disease** show primarily small, mature lymphocytes and occasionally larger, **atypical cells consistent with follicular dendritic cells**. Capillaries are often intermixed with the lymphocytes and reticular cells (Hidvegi et al, 1982; Meyer et al, 1999).

Figure 31-8 Reactive lymphoid hyperplasia. The field shows a lymphoid aggregate containing follicular center cells.

Figure 31-9 Reactive lymphoid hyperplasia. Aspirate shows a polymorphous population composed of small and large cleaved cells, plasmacytoid lymphocytes, and tingible body macrophages (*arrow*) (*A*: Diff-Quik stain, low magnification; *B*: Papanicolaou stain, high magnification.)

Figure 31-10 Reactive lymphoid hyperplasia. Immunocytochemical studies show a polyclonal B-cell population comprising a mixture of kappa- and lambda-positive cells and scattered T-cells (CD3+). There is an elevated proliferative activity with a labeling index of 30% with Ki-67 antibody consistent with a reactive process (Immunoperoxidase stain.)

The **plasma cell variant of Castleman disease** may be localized or multicentric. The **localized form** tends to affect the mediastinum and the intraabdominal lymph nodes. Patients are usually young adults who have **systemic symptoms** such as fever, anemia, and hypergammaglobulinemia. The **multicentric form** is more common in patients who are middle-aged or older and who have peripheral lymphadenopathy; they tend to have more severe systemic symptoms than patients with the localized form. **Multicentric Castleman disease** may also occur in **human immunodeficiency virus (HIV)-infected individuals** in whom it is associated with **human herpesvirus type 8** (Kaposi sarcoma virus). Aspirates show a polymorphous lymphoid population with occasional immunoblasts and **higher than normal numbers of plasma cells**, some of which contain Russell bodies.

Kikuchi lymphadenitis is a self-limited disease of unknown cause that appears to be more prevalent among Asians than Western populations. Most patients are young women who have painful unilateral cervical lymphadenopathy. Infrequently, the lymphadenopathy is generalized. Histologically, there are localized areas of necrosis in cortical or paracortical areas with prominent karyorrhexis but no polymorphonuclear infiltrate. Atypical mononuclear cells and immunoblasts are on the periphery. Some patients have hematologic abnormalities.

Smears taken from such patients show a **heterogeneous population of small and large transformed lymphocytes and tingible body macrophages**. Scattered in the background are necrotic debris and karyorrhectic (apoptotic) cells (Kung et al, 1990; Hseuh et al, 1993; Tsang et al, 1994).

Kimura disease is a chronic inflammatory disorder of unknown origin that may be an aberrant immune reaction to an unknown stimulus. This disease is more prevalent in men than in women among Asian populations. Patients often have painless lymphadenopathy of the head and neck region with cutaneous or subcutaneous nodular lymphoid infiltrates. **Aspirates are consistent with florid reactive lymphoid hyperplasia with Warthin-Finkeldey-type multinucleated**

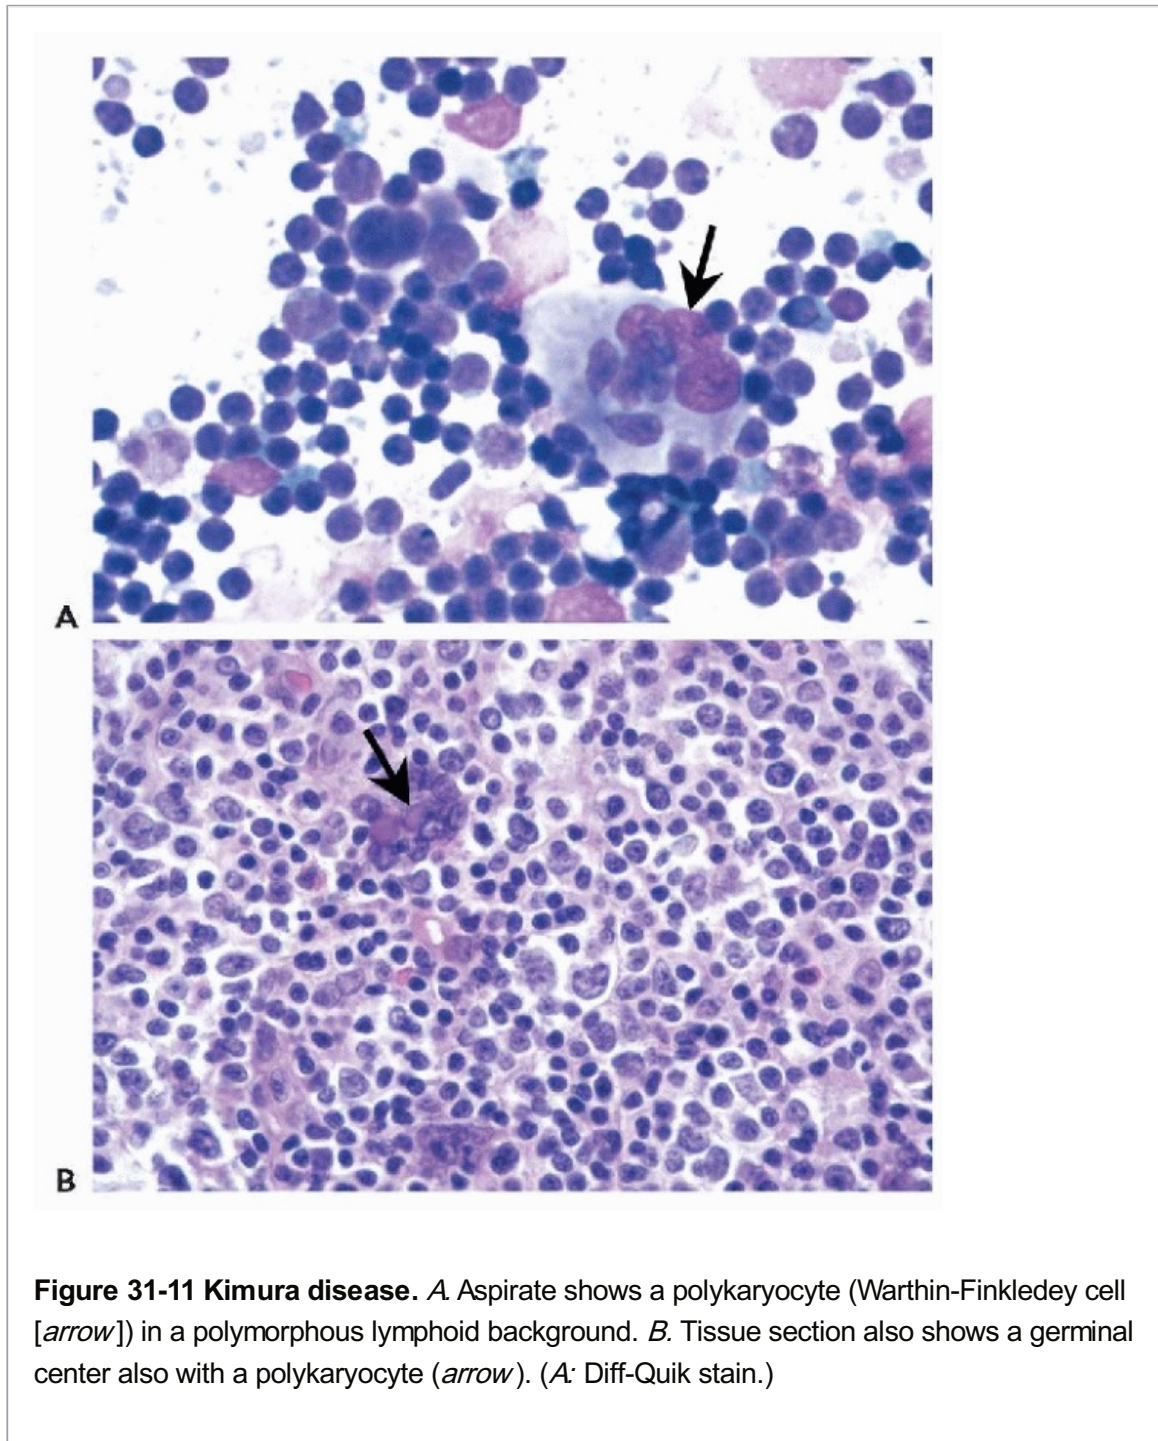

giant cells (Fig. 31-11) and **eosinophils** (Hui et al, 1989).

Dermatopathic Lymphadenopathy

In the presence of chronic skin disorders, lymph node enlargement is common. Histologically, there is **follicular and paracortical hyperplasia** and accumulation of phagocytized **granules of melanin**. Pigment from **tattoos** may mimic melanin accumulation (Zirkin et al, 2001). The principal cells involved are the **interdigitating reticulum cells**

P.1193

that may show complex nuclear contours (Asano et al, 1987).

The most important points of differential diagnosis are: lymphadenopathy associated with cutaneous T-cell lymphoma (see below) and metastatic malignant melanoma (Burke et al, 1986;

Cangiarella et al, 2000).

Viral Infections

Virus infections, such as with the **Epstein-Barr virus (EBV)** and the **human immunodeficiency virus (HIV)**, are usually associated with lymphadenopathy. Occasionally, **cytomegalovirus**, the **measles- and varicella-zoster viruses**, and **herpesvirus** can also affect the lymph nodes. The characteristic viral inclusions are described elsewhere (see Chaps. 10 and 19).

Infectious mononucleosis is associated with EBV. It is a self-limited infectious disease that affects young patients and can result in fever, pharyngitis, rash, and cervical adenopathy. The axillary and inguinal lymph nodes can also be affected. Atypical lymphocytes are present in the peripheral blood. Most of these cases are diagnosed clinically and confirmed with a **heterophil antibody (Monospot) test**. However, some patients may have an unusual presentation of this disease, such as lymphadenopathy without associated symptoms, and their lymph nodes may have to be aspirated to confirm the diagnosis.

Aspirates of infectious mononucleosis can be quite variable, but they usually show a polymorphous population of small and large transformed lymphocytes, immunoblasts with binucleation, tingible body macrophages, plasma cells, eosinophils, and mast cells. **The immunoblastic proliferation may be so florid that it may be mistaken for lymphoma**, but the spectrum of immunoblastic maturation in cells with plasmacytoid features is not seen in lymphomas. **Binucleated immunoblasts, resembling the Reed-Sternberg cells** observed in Hodgkin lymphoma, have been described in infectious mononucleosis and **postvaccinal lymphadenitis**; however, these cells usually do not meet the strict criteria for Reed-Sternberg cells (Kardos et al, 1988; Stanley et al, 1990a).

Infection with Human Immunodeficiency Virus

Individuals infected with HIV commonly have lymphadenopathy. FNA is a useful tool to determine whether the enlarging lymph nodes are related to viral or opportunistic infections, Kaposi sarcoma, high-grade lymphoma, or metastatic carcinoma (Martin-Bates et al, 1990; Strigle et al, 1992). Needle aspiration biopsy and flow cytometry of lymph nodes has been proposed as potentially useful in assessing the clinical status of HIV-infected patients (Cajigas et al, 1997).

HIV lymphadenitis may be associated with a spectrum of changes, ranging from florid lymphoid hyperplasia to marked lymphoid depletion. As in other types of viral lymphadenitis, aspirates from florid lymphoid hyperplasia typically show a **heterogeneous population** of small, intermediate, and large lymphocytes; plasma cells; and tingible body macrophages (Oertel et al, 1990; Shabb et al, 1991). **Multinucleated giant cells or polykaryocytes with multiple small nuclei that resemble osteoclasts (Warthin-Finkeldey cells, also seen in measles) and epithelioid histiocytes** have also been observed. Oertel et al (1990) noted that lymph node aspirates from HIV-positive patients contained a higher number of immunoblasts than did those from HIV-negative patients. **In some cases, the presence of numerous immature cells may be suggestive of lymphoma** (Fig. 3-12). Immunophenotyping is usually helpful in confirming a **polyclonal population**.

In the **depletion phase**, aspirates often have sparse follicular center cells, immunoblasts, and tingible body macrophages but **high numbers of plasma cells**. Macrophages may also be seen. In such cases, infections caused by mycobacteria and fungi should be ruled out.

Granulomatous Lymphadenitis

In histologic sections, the presence of **granulomas**, composed of epithelioid and giant cells with or without central necrosis, is the hallmark of granulomatous lymphadenitis. Granulomas are approximately spherical structures of various

P.1194

sizes, composed of **elongated epithelioid cells** with pale, eosinophilic cytoplasm and **giant cells, usually of Langhans type**, with a garland of peripheral, small nuclei. Granulomatous lymphadenitis can be seen, not only in infectious processes such as **tuberculosis, atypical mycobacteriosis, brucellosis**, or infections caused by **fungi** or ***Pneumocystis carinii***, but also in **sarcoidosis, foreign-body reactions, non-Hodgkin lymphoma, Hodgkin lymphoma**, and, rarely, **lymph node-draining carcinoma**.

Figure 31-12 Reactive lymphoid hyperplasia. *A,B.* An increased number of transformed lymphocytes and paraimmunoblasts are present in this aspirate from a patient infected with human immunodeficiency virus. *C.* High magnification of the tissue section shows a

spectrum of lymphoid cells including small lymphocytes, intermediate-size transformed cells, and immunoblasts. (A: Diff-Quik stain; B: Papanicolaou stain; A,B: oil immersion.)

Cytology

In aspirates, granulomatous lymphadenitis is characterized by **epithelioid histiocytes in a background of lymphocytes and plasma cells**. **Epithelioid histiocytes are elongated polygonal cells with pale cytoplasm, indistinct cell borders, and elliptical, sometimes comma- or boomerang-shaped pale nuclei with finely granular chromatin, and frequently slight lateral indentations** (Fig. 31-13). These cells may form loose aggregates or cohesive clusters that are reminiscent of granulomas when seen in tissue sections.

Multinucleated giant cells of foreign-body-type with dispersed nuclei or Langhans type giant cells are often present. Granulomatous lymphadenitis may or may not show **associated necrosis**, which appears as acellular granular material on smears.

Figure 31-13 Granulomatous lymphadenitis. A. Epithelioid histiocytes and lymphocytes are seen in an aspirate from a patient with tuberculosis. B. Tissue section shows

granulomas composed of epithelioid histiocytes and a Langhans-type giant cell.

Conditions Associated with Granulomatous Lymphadenitis

Mycobacterial infections, including those caused by *Mycobacterium tuberculosis* and **atypical mycobacteria**, are associated with granulomatous lymphadenitis. World-wide, tuberculosis is the leading infectious cause of morbidity and mortality. In the United States, the number of new cases of tuberculosis has increased over the last decade, primarily in areas where HIV infection is prevalent. Individuals at high risk for tuberculosis include infants and young children, elderly adults, and immunocompromised patients such as those infected with HIV.

Very rarely, smears from the lymph nodes of patients with **tuberculous lymphadenitis may show only necrotic material and neutrophils** (Das, 2000). The presence of **negative images of bacilli** (Fig. 31-14) on air-dried Romanovsky's stained smears is a helpful diagnostic clue that

P.1195

the lymph node is infected by mycobacteria (Stanley et al, 1990b; Ang et al, 1993). The acid-fast bacillus stain can be performed even on destained Papanicolaou-stained smears to identify mycobacterial organisms, although the detection rate is quite variable with this method.

Figure 31-14 Mycobacterial infection. *A.* Negative-images (*arrow*) of mycobacterial bacilli are seen in air-dried smears from a patient who had lymphadenopathy thought to be caused by lymphoma. *B.* Acid-fast stain shows long, beaded, filamentous bacilli (*arrow*) that were classified as *Mycobacterium kansasii* by culture. (*A:* Diff-Quik stain; *B:* Ziehl-Neelsen stain; *A,B:* oil immersion.)

Mycobacterium avium-intracellulare infection should be considered when aggregates of large histiocytes are filled with negatively stained linear cytoplasmic inclusions, particularly in patients who are immunosuppressed (Shabb et al, 1991). In lepromatous leprosy, the characteristic cell is a syncytial histiocyte (Virchow or globus cell), which is frequently multinucleated and has a vacuolated cytoplasm that contains numerous lepra bacilli (Gupta et al, 1981).

Fungal infections, previously discussed in depth in Chapter 19, such as those caused by *Histoplasma capsulatum*, *Coccidioides immitis*, and *Cryptococcus neoformans*, may involve lymph nodes. Chaiwun et al (2002) reported eight HIV-positive patients with lymphadenopathy caused by *Penicillium marneffe*. The Gomori's methenamine silver stain is

helpful in detecting these organisms in cytologic preparations.

Histoplasmosis is endemic in the central part of the United States, while **coccidioidomycosis** is endemic in the southwestern regions. Histoplasmosis involving the mediastinal lymph nodes may be associated with inflammation and proliferation of fibrous tissue resulting in **sclerosing mediastinitis**. Aspirates of lymph nodes from patients with coccidioidomycosis often show extensive necrosis; careful examination may reveal thick-walled cysts containing endospores (Fig. 31-15). **Cryptococcus** may affect both immunocompetent and immunosuppressed patients. Aspirates of lymph nodes from infected patients show epithelioid histiocytes, yeast-filled giant cells, and lymphocytes (Fig. 31-16). The narrow-based budding yeasts usually have a thick mucopolysaccharide capsule that stains positive with mucicarmine stain. The Fontana-Masson stain, which provides the advantage of staining capsule-deficient organisms, can also be used (Ro et al, 1987).

Lymphadenitis in toxoplasmosis usually affects the posterior cervical lymph nodes, although other lymph nodes may be involved. Infection most commonly results from exposure to contaminated cat feces or ingestion of undercooked meat. Aspirates show a polymorphous lymphoid

P.1196

population admixed with loosely aggregated epithelioid histiocytes and tingible body macrophages. The crescent-shaped organisms are rarely observed in aspirates (Argyle et al, 1983). ***Pneumocystis carinii***, discussed at length in Chapter 19, can also cause granulomatous lymphadenitis in AIDS.

Figure 31-15 *Coccidiomycosis immitis*. *A*. Smear shows a spherule in a background of acute inflammatory cells. *B*. Cell block shows an aggregate of lymphocytes, epithelioid histiocytes, and a multinucleated giant cell in a background of necrosis. *C*. A mature spherule contains endospores (*arrow*). (*A*: High magnification; *B*: H & E stain; *C*: Gomori's methenamine silver stain, high magnification.)

Gomori methenamine silver stain shows yeast (*arrow*) varying in size with occasional narrow-based budding. C. A mucicarmine stain highlights the thick mucopolysaccharide capsule. (A-C: Oil immersion.)

Lymphadenitis associated with **rhinoscleroma** was reported by Gera et al (1995). Large macrophages, known as **Mikulicz cells**, containing Gram-negative bacteria, were observed.

Sarcoidosis is a granulomatous disease of unknown cause that affects blacks more frequently than whites. The disease is usually diagnosed in the third and fourth decades of life. It can affect any organ, including cervical and hilar lymph nodes (Frable and Frable, 1984; Morales et al, 1994). For a discussion of the cytologic presentation of sarcoidosis, see Chapter 19.

Similar granulomas may occur in lymph nodes draining metastatic cancer.

Cat-scratch disease is caused by a pleomorphic Gram-negative bacillus, *Bartonella henselae*. The disease should be suspected if the aspirate from an axillary or neck lymph node reveals granulomatous inflammation accompanied by neutrophils, necrosis, and occasional

multinucleated giant cells (**suppurative granulomatous inflammation**) (Fig. 31-17) in a young patient who has had close contact with a cat.

Figure 31-17 Suppurative granulomatous inflammation. *A.* Inflammatory cells are admixed with epithelioid histiocytes in this aspirate from a patient whose clinical history was consistent with **cat-scratch disease**. *B.* Tissue sections show neutrophils, histiocytes, and extensive necrosis. *C.* Small aggregates of bacteria are visible on the Warthin-Starry stain. (*B,C*: high magnification.)

Lymphogranuloma venereum, caused by *Chlamydia trachomatis*, should be considered when the aspirate of an inguinal lymph node exhibits suppurative granulomatous inflammation (see Chap. 10). Similar findings may be observed in the rare **tularemia** (caused by *Francisella tularensis*, transmitted from rabbits and other rodents) and in the abdominal lymph nodes in the equally rare intestinal infection by the Gram-negative organism *Yersinia (enterocolica or pseudotuberculosis)*.

Sinusoidal Expansion Of Lymph Nodes

Sinus histiocytosis is a common type of lymph node hyperplasia that affects mainly the axillary and inguinal areas. This type of hyperplasia **may also be observed in lymph nodes that drain cancers**. In histologic sections of lymph

P.1197

nodes, the markedly dilated sinuses are filled with macrophages that have abundant, foamy cytoplasm. In aspirates, a few macrophages with phagocytic material and occasional neutrophils are seen.

Conditions Associated with Sinusoidal Expansion

Sinus histiocytosis with massive lymphadenopathy, also known as **Rosai-Dorfman disease**, is a benign, generally self-limited condition. It usually affects children and adolescents, occurs more frequently in black than white patients, and is characterized by bilateral cervical lymphadenopathy, leukocytosis, and an elevated erythrocyte sedimentation rate. **Aspirates usually contain numerous histiocytes, some containing whole lymphocytes within their cytoplasm** (a phenomenon known as **emperipolesis**) (Fig. 31-18), plasma cells, and few neutrophils (Pettinato et al, 1990; Deshpande et al, 2000).

Langerhans cell histiocytosis is a rare disorder, usually occurring in children and young adults. It most commonly presents as a single lytic bone lesion (**eosinophilic granuloma**), composed of mature, lipid-laden histiocytes, **Langerhans' cells** with pale eosinophilic cytoplasm, and a finely textured characteristically **indented or grooved nuclei** and varying numbers of eosinophils, plasma cells, and neutrophils with a few multinucleated giant cells. Less commonly, Langerhans-cell histiocytosis is multifocal and may involve soft tissue including lymph nodes, sometimes with the triad of **Hand Schuller Christian disease** (exophthalmos, diabetes insipidus, and bone defects). **Langerhans cells** are dendritic cells, normally present in the epidermis and other epithelia, and are thought to play a role in the immunologic response of the skin. They are **antigen-presenting cells** characterized by **expression of CD-1a antigen** and the presence of tennis racquet-shaped tubular cytoplasmic structures (**Birbeck granules**) on ultrastructural examination. **In needle aspirates, the Langerhans cells have a striking similarity to the macrophages observed in sinus histiocytosis, except for their convoluted and grooved nuclei and the absence of phagocytosis** (Koss et al, 1992). **Their identity can be confirmed by staining with CD-1a antibody**. Needle aspiration smears usually also contain **eosinophils and multinucleated giant cells, plasma cells, and neutrophils; the presence of eosinophils should always alert one to this diagnosis** (Pohar-Marinsek and Us-Krasovec, 1996; Kakkar et al, 2001).

Figure 31-18 Sinus histiocytosis with massive lymphadenopathy. *A.* Numerous histiocytes (macrophages) are present. *B.* Note the histiocyte (macrophage) with emperipolesis (*arrow*). (*A*: Diff-Quik stain, high magnification; *B*: Papanicolaou stain, oil immersion.)

Phagocytosis of foreign material may be associated with lymphadenopathy. In the past, lymphangiography was performed to visualize retroperitoneal lymph nodes in suspected lymphoma or metastatic carcinoma. A radio-opaque oily material, injected into the lymphatics of the dorsum of the foot, is transported to retroperitoneal lymph nodes and phagocytized by macrophages. Aspiration of such lymph nodes results in the so-called **lymphangiogram effect**. The smears show large, lipid-laden histiocytes, multinucleated giant cells, and eosinophils. Leaking or rupture of **silicone implants** used in breast augmentations or joint prostheses may result in silicone reaching the regional lymph nodes, which are generally enlarged. Aspirates from the lymph nodes of such patients may show silicone lymphadenopathy, which is characterized by the presence of numerous **vacuolated macrophages and multinucleated giant cells. The vacuoles contain silicon, a refractile homogeneous material that is not birefringent. Asteroid bodies**, which are crystalloid

structures resembling stars, may be seen in the cytoplasm of the macrophages (Tabatowski et al, 1990; Dodd et al, 1993). It is of interest that **asteroid bodies may also be observed in sarcoidosis** (see Chap. 19).

POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISORDERS

Posttransplantation lymphoproliferative disorders occur in approximately 2% of organ-transplant recipients who were given immunosuppressive therapy. **Epstein-Barr virus (EBV)** is commonly associated with these disorders. Their recognition is important because, unlike conventional lymphomas, they may respond to a decrease in the dosage of immunosuppressive treatments, whereas continued immunosuppression may lead to disease progression. Further, these disorders may not respond to conventional chemotherapy (Knowles et al, 1995).

P.1198

Aspirates from patients who have posttransplantation lymphoproliferative disorder may have either a polymorphous or monomorphous cell population. In the former, aspirates show a heterogeneous population of mature and immature lymphocytes, with scattered plasma cells and histiocytes in the background, whereas aspirates from the latter contain predominantly large cells resembling lymphoma (Gattuso et al, 1997; Dusenbery et al, 1997).

Knowles et al (1995) classified posttransplantation lymphoproliferative disorders into three categories according to distinct morphologic and molecular findings:

- **Plasmacytic hyperplasia**
- **Polymorphic B-cell hyperplasia and polymorphic B-cell lymphoma**
- **Immunoblastic lymphoma or multiple myeloma**

In **plasmacytic hyperplasia**, the cells are usually polyclonal, contain multiple forms of EBV, and lack oncogene and tumor suppressor gene alterations. In **polymorphic B-cell hyperplasia and polymorphic B-cell lymphoma**, cells are usually monoclonal, contain a single form of EBV, and lack oncogene and tumor suppressor gene alterations. The patients with **immunoblastic lymphoma or multiple myeloma** have widespread disease and the cells are monoclonal, contain a single form of EBV, and have alterations of one or more oncogenes or tumor suppressor genes. For further discussion of these entities, see below.

MALIGNANT LYMPHOMAS

In the past, the principal role of FNA of lymph nodes was to determine the presence of metastatic carcinoma or sarcoma. The idea that one could diagnose and subclassify lymphoid neoplasms by FNA was met with skepticism by pathologists and clinicians (Hajdu and Melamed, 1984). Although the presence of an atypical lymphoid population was recognized on FNA specimens in most instances of lymphoma, a definitive diagnosis of lymphoma was usually rendered only on excised lymph nodes. Over the last two decades, there has been a gradual increase in the number of publications that document the value of FNA in the diagnosis and subclassification of non-Hodgkin **lymphomas in conjunction with ancillary studies**, from several institutions (Ramzy et al, 1985; Carter et al, 1988; Frable and Kardos, 1988; Cardillo, 1989; Cafferty et al, 1990; Sneige et al, 1990; Gupta et al, 1991; Suhrland and Wiecezorek, 1991; Moriarty et al, 1993; Steel et al, 1994; Prasad et al, 1996; Dunphy and Ramos, 1997; Jeffers et al, 1998; Wakely et al, 1998; Young et al, 1998; Das, 1999; Meda et al, 2000; Nasuti et al, 2000; Nicol et al, 2000). However, even **in some of these institutions, FNA is used**

primarily to document residual or recurrent lymphoma or to assess the stage of the disease. The use of FNA to render a primary diagnosis of lymphoma remains controversial (Frable and Kardos, 1988; Kardos et al, 1986; Hehn et al, 2004).

Many of the limitations of FNA in the diagnosis of lymphoproliferative disorders have been addressed by Katz and Caraway (1995). One of the major drawbacks to the use of FNA is the lack of lymph node architecture that is important in the subclassification of some lymphomas. However, because many lymphomas have distinctive cytomorphologic, immunophenotypic, and proliferative profiles, the absence of architecture can be overcome in these instances by immunophenotyping. **A subsequent lymph node excision should always be performed if the material is inadequate, if the results are ambiguous, or if the clinical and radiographic findings are not in accord with the cytologic interpretation.**

Classification of Lymphomas

Over the last 50 years, several systems have been proposed to classify malignant lymphomas. New systems have been formulated as the sequence of events in the turnover and maturation of lymphocytes has become better understood. Three discoveries were especially important in this process: the first was the observation that the basic characteristics of normal B and T lymphocytes may be retained by the lymphoma cells; the second was the recognition that small lymphocytes are a resting form of the cell that can undergo a series of notable metamorphoses, leading to the formation of large, metabolically active cells; and the third was the recognition that non-Hodgkin lymphomas exhibit both diffuse and nodular or follicular forms. In the latter form, the tumor tends to mimic the formation of lymphoid follicles and, sometimes, their germinal centers.

Early classification systems used primarily tissue architecture, the cytologic features of the cells, or both. In the 1980s, the complexity of the Rappaport (1966), Lukes and Collins (1974), and Lennert from Kiel (1967) classification systems prompted the U.S. National Cancer Institute to classify non-Hodgkin lymphomas into groupings with some prognostic value (Koss et al, 1992). The resulting classification, known as the **Working Formulation** (non-Hodgkin pathologic project, 1982) of non-Hodgkin lymphomas had three grades: low, intermediate, and high, all three derived strictly from morphologic appearance. Since then, remarkable progress has been made in our understanding of lymphomas on the basis of laboratory findings such as morphologic features, immunophenotype, cytogenetic features, molecular analysis, and clinical manifestations and course of the disease (Jaffe et al, 1999). The information from these findings has been used to develop the **Revised European-American Classification of Lymphoid Neoplasms (REAL)**, proposed by the International Lymphoma Study Group (Harris et al, 1994). The REAL system categorizes entities on the basis of the neoplasm's cell of origin. Because this system places greater emphasis than previous systems on cytomorphologic features, immunophenotype, and results of molecular studies, it can be applied easily, using a multiparameter approach to FNA specimens. The new (1998) World Health Organization (WHO) classification for lymphomas (Table 31-3) is similar to the REAL system; minor modifications have been made as additional data have become available (Jaffe et al, 1999).

P.1199

TABLE 31-3 WORLD HEALTH ORGANIZATION CLASSIFICATION OF THE NEOPLASTIC DISEASES OF THE LYMPHOID TISSUES

B-Cell Neoplasms

Precursor B-cell lymphoblastic leukemia/lymphoma

Mature B-cell neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma

Prolymphocytic leukemia

Lymphoplasmacytic lymphoma (lymphoplasmacytoid lymphoma)

Mantle cell lymphoma

Follicular lymphoma (follicle center lymphoma)

Marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type

Nodal marginal zone lymphoma with or without monocytoid B-cells

Splenic marginal zone B-cell lymphoma

Hairy cell leukemia

Diffuse large B-cell lymphoma

Subtypes: mediastinal (thymic), intravascular, primary effusion lymphoma

Burkitt lymphoma

Plasmacytoma

Plasma cell myeloma

T-Cell and NK-cell Neoplasms

Precursor T-cell lymphoblastic leukemia/lymphoma

Mature T-cell and NK-cell neoplasms

T-cell prolymphocytic leukemia

T-cell large granular lymphocytic leukemia

NK-cell leukemia

Extranodal NK/T-cell lymphoma, nasal-type (angiocentric lymphoma)

Mycosis fungoides

Sézary syndrome

Angioimmunoblastic T-cell lymphoma

Peripheral T-cell lymphoma (unspecified)

Adult T-cell leukemia/lymphoma (HTLV1+)

Systemic anaplastic large cell lymphoma (T- and null-cell types)

Primary cutaneous anaplastic large cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma

Enteropathy-type intestinal T-cell lymphoma

Hepatosplenic γ/Δ T-cell lymphoma

Hodgkin Lymphoma (Hodgkin Disease)

Nodular lymphocyte predominance Hodgkin's lymphoma

Classic Hodgkin lymphoma

Hodgkin lymphoma, nodular sclerosis type (grades I and II)

Classic Hodgkin lymphoma, lymphocyte-rich

Hodgkin lymphoma, mixed cellularity

Hodgkin lymphoma, lymphocytic depletion (includes some "Hodgkin-like anaplastic large cell lymphoma")

Modified from Jaffe et al, 1999 with permission.

NK, natural killer cells; HTLV, human T-cell lymphoma virus; +, positive.

This chapter highlights the B-cell lymphomas, which are the most common in everyday practice. T-cell lymphomas are briefly discussed but not all the lymphomas listed in the REAL or updated WHO classifications are discussed.

Principles of Cytologic Diagnosis of Malignant Lymphomas

The population of cells in non-Hodgkin's lymphomas is usually monotonous, that is, the cells are of approximately equal sizes. There are some exceptions to this rule, described below. Cells of malignant lymphomas in well-prepared smears appear singly and do not form clusters. In poorly prepared smears, overlapping of cells may sometimes be observed. In assessing smears, the lymphoid cells are classified as “small” if they are equal in size or slightly larger than normal resting lymphocytes; “intermediate” if they are one and one-half times larger than the size of a normal lymphocyte but not larger than the nucleus of a macrophage; or “large” if they are two or more times the size of a normal lymphocyte.

The nuclei may be **round, cleaved, or lobulated**, or **show irregularities of the membrane** with small protrusions. The coarse or fine patterns of chromatin distribution and the presence or absence of nucleoli must be noted.

Lymphoglandular bodies (Søderstrøm bodies) discussed in the opening pages of this chapter, are helpful in recognizing the lymphocytic origin of a neoplasm if the cell population is difficult to classify, as is sometimes the case in large-cell lymphomas. Although Bangerter et al (1997) considered the Søderstrøm bodies to be specific for malignant lymphomas and related disorders, they are commonly observed in benign aspirates and, rarely, in other malignancies as well.

B-Cell Lymphoma

Mature B-cell lymphomas comprise the majority of lymphoid neoplasms worldwide and are more common in developing countries. The subclassification of these neoplasms requires a multiparameter approach.

Small Lymphocytic Lymphoma

Most cases of the small lymphocytic lymphomas occur in older adults, and most patients have bone marrow and peripheral blood involvement, although occasionally the disease is limited to the lymph nodes. Many patients with the latter form eventually develop disease in the bone marrow and blood. The clinical course is indolent but the disease is not curable. The disease may undergo transformation into prolymphocytic lymphoma, large-cell lymphoma (Richter syndrome), or, rarely, Hodgkin lymphoma.

Cytology

Small lymphocytic lymphoma comprises a monomorphous population of small, round lymphocytes with nuclei that have a checkerboard pattern of clumped chromatin, known as “cellules grumelées” (Fig. 31-19). For a detailed discussion of these cells see Chapters 26 and 27. Scattered in the background are large cells—prolymphocytes and paraimmunoblasts. Prolymphocytes are slightly larger than paraimmunoblasts, but both have round nuclei with prominent nucleoli and gray-blue cytoplasm.

An increase in the numbers of paraimmunoblasts (Fig. 31-20) may indicate a more aggressive clinical course than that of typical small lymphocytic lymphoma (Pugh et al, 1988).

Other cytologic manifestations of unfavorable accelerated course are plasmacytoid cells, mitotic figures, apoptotic bodies, necrosis, and a myxoid, dirty background (Shin et al, 2003). The predominance of large cells is indicative of a transformation of small cell lymphoma into a large B-cell lymphoma (**Richter lymphoma**).

Ancillary Studies

Immunophenotyping demonstrates a light chain restriction to either kappa or lambda expression (Fig. 31-21) and positivity for B-cell-associated antigens (CD19 and CD20), CD5, CD43, and CD23, but negativity for

P.1201

CD10 and FMC7. DNA ploidy analysis of small lymphocytic lymphoma shows a **diploid population with low proliferative activity** (mean Ki-67 labeling index of 5%) (Katz, 1993c), whereas transformed large-cell lymphomas have high proliferative activity.

Figure 31-19 Small lymphocytic lymphoma. *A,B.* Aspirate is composed predominantly of small round cells with clumped chromatin and rare paraimmunoblasts (*arrow*). *C.* Tissue section shows a diffuse infiltrate of small lymphocytes with occasional paraimmunoblasts. (*A:* Diff-Quik stain; *B:* Papanicolaou stains.)

Figure 31-20 Small lymphocytic lymphoma with increased paraimmunoblasts. The increased number of paraimmunoblasts and presence of mitotic figures are suggestive of an accelerated phase of small lymphocytic lymphoma. (Diff-Quik stain.)

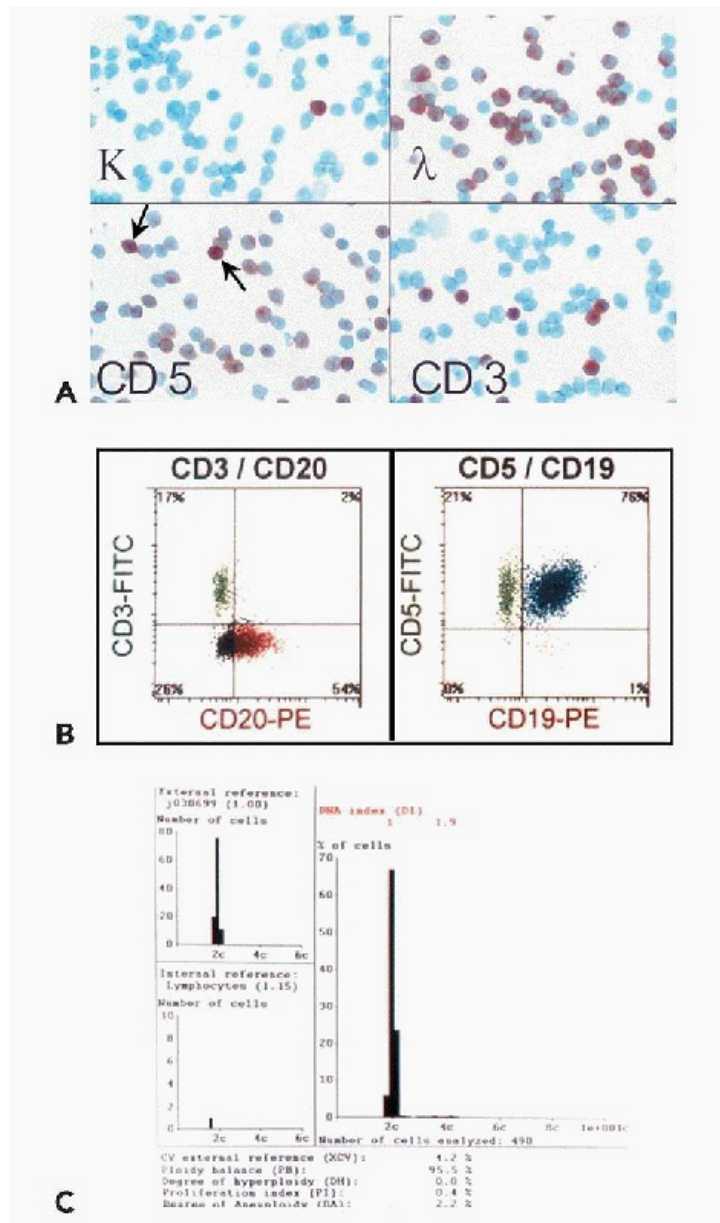

Figure 31-21 Small cell lymphocytic lymphoma. *A.* Immunocytochemical studies show monoclonal staining for lambda and CD5 positivity. Note that the CD5 staining is fainter in the B cells than in the T cells (*arrows*). *B.* Flow cytometry shows T-cell (CD3+) and B-cell (CD20+) population. There are also cells with CD19 and CD5 coexpression. *C.* DNA ploidy by image analysis reveals a diploid cell population and no proliferation index indicative of a low-grade lymphoma. (*A:* Immunoperoxidase stain.)

Trisomy 12 is present in one-third of small lymphocytic lymphoma (Knuutila et al, 1986). It may be demonstrated by FISH on cytospin aspirations with a centromeric probe (Caraway et al, 2000). Deletion of chromosome 13q14 is more common than trisomy 12 (Najfeld, 2003). Immunoglobulin heavy and light chain genes are rearranged (Harris et al, 1994).

Differential Diagnosis

Although both small lymphocytic lymphoma and mantle cell lymphoma show aberrant coexpression of CD5 and CD19 and lack CD10, **small lymphocytic lymphoma is positive for CD23, whereas mantle cell lymphoma is not. Both follicular lymphoma and marginal**

zone lymphoma are CD5 negative. Lymphocyte-predominant Hodgkin lymphoma should be considered if **pale polyploid cells with prominent nucleoli (so-called lymphohistiocytic, L&H, or “popcorn” cells)** appear in a background of mature lymphocytes instead of paraimmunoblasts.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma occurs primarily in older adults and can involve the bone marrow, lymph nodes, and spleen; peripheral blood and extranodal sites are less frequently affected. Most patients have an **elevated level of monoclonal serum paraprotein of the immunoglobulin M** type that sometimes results in symptoms of hyperviscosity (Waldenström macroglobulinemia).

Cytology

Smears of lymphoplasmacytic lymphoma show numerous small lymphocytes, plasmacytoid, and plasma cells. Occasionally, intranuclear inclusions known as **Dutcher bodies** may be observed.

Ancillary Studies

Immunophenotyping shows light-chain restriction, positive staining for B-cell-associated antigens (CD19 and CD20), negative staining for CD5, CD10, and CD23, and variable staining for CD43. DNA ploidy analysis usually shows a **diploid cell population with low proliferative activity**.

Immunoglobulin heavy chain and light chain genes are rearranged, but **there is no single known chromosomal abnormality** that is considered characteristic of lymphoplasmacytic lymphoma.

Differential Diagnosis

In contrast to lymphoplasmacytic lymphoma, small lymphocytic and mantle cell lymphomas are CD5 positive. In addition, mantle cell lymphoma has a more homogeneous cell population. Reactive processes, such as Castleman's disease, can show a predominance of plasma cells, but these lesions are polyclonal.

P.1202

Mantle Cell Lymphoma

Mantle cell lymphoma usually occurs in older adults, mostly men. At the time of diagnosis, the disease is often widespread and can involve the lymph nodes, spleen, bone marrow, blood, and extranodal sites. It is more aggressive than the other B-cell, non-Hodgkin lymphomas that are composed of small cells; patients have a median survival time of 3 to 5 years.

Cytology

Classic mantle cell lymphoma usually consists of a monomorphous population of small to intermediate cells with nuclear membrane irregularities and indentations, fine nuclear chromatin, inconspicuous nucleoli, and scant cytoplasm (Fig. 31-22). In some cases, the nuclei are round or only slightly irregular, whereas others contain markedly angulated and cleaved nuclei. Paraimmunoblasts are absent (Wojcik et al, 1995).

In approximately 20% of mantle cell lymphomas, the neoplastic cells are larger than

usual and have a blastoid appearance, i.e., contain large, irregular nucleoli. Such cases are called the blastoid variant of mantle cell lymphoma that tends to have a more aggressive clinical course than the conventional type (Weisenburger and Armitage, 1996). The blastoid variant may have a monomorphous population of intermediate to large cells (Hughes et al, 1998) or a mixture of atypical small cells and larger blastic cells (Weisenburger and Armitage, 1996). The nuclei have irregular contours, finely dispersed chromatin, and multiple small nucleoli (Fig. 31-23). Mitotic figures and apoptotic bodies may be scattered in the background (Hughes et al, 1998).

Figure 31-22 Mantle cell lymphoma, classic type. *A,B.* Aspirate shows a monomorphic population of small to intermediate cells with cleaved nuclei. *C.* Tissue section shows a diffuse infiltrate of small lymphocytes. (*A:* Diff-Quik stain; *B:* Papanicolaou stain.)

Ancillary Studies

Immunophenotyping demonstrates the expression of B-cell-associated antigens (CD19

and CD20), CD5, CD79b, and FMC7, and negative staining for CD10 and CD23. Usually lambda light chain restriction is more common than kappa light chain restriction. On tissue sections, mantle cell lymphoma typically shows **positive immunostaining for cyclin D1**; however, in our laboratory, immunostaining for cyclin D1 on cytopsin preparations has been variable.

DNA ploidy analysis of **classic mantle cell lymphoma usually shows a diploid population with low-to-intermediate proliferative activity** (Wojcik et al, 1995). In contrast, the blastoid variant often shows a tetraploid population (Ott et al, 1997) with high proliferative activity, which is consistent with high-grade lymphoma (Hughes et al, 1998).

Mantle cell lymphoma has a **characteristic chromosomal t(11;14) (q13q32) translocation** that involves the immunoglobulin heavy chain locus and the *bcl-1* locus on the long arm of chromosome 11. **This translocation results in overexpression of the *PRAD/bcl-1* gene that encodes for cyclin D1**, a cell-cycle protein (Rimokh et al, 1994). The polymerase chain reaction (PCR) detects breakpoints in the major translocation cluster region of *bcl-1*; however, the test is positive in only 50% of mantle cell lymphomas (Rimokh et al, 1994). The t(11;14) translocation can be demonstrated by FISH on cytopsin preparations (Caraway et al, 1999; Katz et al, 2000) (Fig. 31-24).

Figure 31-23 Mantle cell lymphoma, blastoid variant. In contrast to Figure 31-22, this variant is composed of large cells with nuclei containing fine chromatin and several small nucleoli. Note abundant apoptosis. (Papanicolaou stain, high magnification.)

Figure 31-24 Mantle cell lymphoma. The cell in the center shows two fusion signals (arrow) indicative of the t(11;14) translocation: one orange signal representing the non-translocated cyclin D1 gene on chromosome 11 and one green signal representing the nontranslocated immunoglobulin gene on chromosome 14. (Interphase FISH, oil immersion.) (FISH picture courtesy of Dr. Jun Gu.)

Differential Diagnosis

The smears of most mantle cell lymphomas are uniformly composed of small lymphoid cells, whereas smears of small-cell lymphocytic lymphomas and follicular lymphomas have a component of larger paraimmunoblasts and centroblasts. Immunophenotyping is also helpful. Although both mantle cell lymphoma and small lymphocytic lymphoma are CD5 positive and CD10 negative, only the latter is positive for CD23. Follicular lymphomas express CD10 but are CD5 negative. **Marginal zone lymphoma** is also a diagnostic consideration, but it usually has a far more heterogeneous population of cells—including monocytoid B cells, plasma cells, and centroblasts—than mantle cell lymphoma; furthermore, marginal zone lymphoma is negative for CD5 (see below).

Marginal Zone and MALT Lymphoma

Marginal zone lymphoma is a rare low-grade, B-cell neoplasm that can have several clinical manifestations, including the involvement of extranodal sites, lymph nodes, the spleen, and the gastrointestinal tract. Each of these is considered a distinct entity in the updated WHO classification system (Jaffe et al, 1999). **Extranodal marginal zone lymphoma is also known as mucosa-associated lymphoid tissue lymphoma (MALT), and most patients have localized disease.** MALT lymphomas involving organs of the gastrointestinal tract are discussed in Chapter 24. Nodal marginal zone lymphoma is also known as monocytoid B-cell lymphoma (Issacson, 1990; Ngan et al, 1991). Splenic marginal zone lymphoma may, or may not, have villous lymphocytes (Harris et al, 1994).

Cytology

Lymph node aspirates from patients with marginal zone lymphoma can be quite variable but usually have a heterogeneous population of monocytoid cells, small cleaved cells, large noncleaved cells, and plasma cells (Fig. 31-25). The monocytoid cells are of intermediate size with moderate to abundant amounts of pale cytoplasm; they may have a plasmacytoid appearance. The nuclei can be somewhat variable with oval or reniform nuclei, vesicular or coarse chromatin, and inconspicuous nucleoli. Tingible body macrophages have also been observed in some cases (Matsushima et al, 1999).

Ancillary Studies

Immunophenotyping usually demonstrates cells that stain positive for B-cell-associated antigens (CD19, CD22, and CD20) and negative for CD5, CD10, CD23, and CD103.

DNA ploidy analysis shows low proliferative activity.

There are no rearrangements of the *bcl-1* or *bcl-2* genes. Trisomy 3 and the t(11;18), (q21;q21) translocations have been reported in extranodal marginal zone lymphomas (Harris et al, 1994).

Differential Diagnosis

Because both marginal zone lymphoma and reactive processes can have heterogeneous cell populations, **immunophenotyping is essential** in determining whether the cells are monoclonal or polyclonal. Small lymphocytic lymphoma and mantle cell lymphoma can be differentiated by their CD5 positivity, whereas follicular lymphomas are positive for CD10. Differentiating lymphoplasmacytic lymphoma from marginal zone lymphoma may be difficult because both contain plasmacytoid cells. **Hairy cell leukemia** also can involve the spleen and lymph nodes and should be differentiated from marginal zone lymphoma (Young and Al-Saleem, 1999). Besides their characteristic morphology with numerous long microvilli ("hairs") on the surface of the tumor cells, the **cells in hairy cell leukemia are positive for the mucosal T-lymphocyte antigen CD103**. This antigen is helpful in distinguishing hairy cell leukemia from other B-cell lymphomas, which are negative for this antigen (Jennings and Foon, 1997).

Figure 31-25 Marginal zone lymphoma. Aspirate shows a polymorphous lymphoid population with some cells having a monocytoid appearance. (Diff-Quik stain, high magnification.)

P.1204

Follicular Lymphomas

Follicular lymphomas (FLs) are B-cell neoplasms composed of a mixture of cleaved follicle center cells (centrocytes) and large noncleaved follicle center cells (centroblasts). FLs recapitulate the follicular architecture of the lymph node, at least focally, although diffuse areas of lymphoma may also be present. Well-prepared smears from the lymph node involved by FL may show **follicular or nodular aggregates of follicle center cells.** However, since the architectural pattern is a prognostic indicator and cannot be reliably assessed on FNA specimens, **we advocate performing an excisional biopsy at the time of the initial diagnosis to allow for further classification of these tumors.**

In the REAL classification, the FLs are subdivided into **three cytologic grades:** I, predominantly small cells; II, mixed small and large cells; and III, predominantly large cells (Harris et al, 1994). The decision to institute anthracycline therapy is based on grading (Rigacci et al, 2003).

Cytology

Smears of follicular lymphomas are composed of a mixture of small, irregular lymphocytes and larger cells. The lymphocytes, only slightly larger than normal lymphocytes, have nuclei showing irregular contours and inconspicuous nucleoli. The larger cells are centroblasts characterized by sharply demarcated basophilic cytoplasm and round, non-cleaved nuclei with finely granular chromatin and 2 to 3 peripheral nucleoli (Fig. 31-26). Centroblasts must be differentiated from centrocytes with cleaved nuclei and follicular dendritic cells, characterized by wispy cytoplasm, indented reniform nuclei, and small nucleoli. An increase in the proportion of centroblasts indicates a higher grade of FL (Fig. 31-27).

As mentioned above, it has been recognized for many years that smears of follicular lymphoma contain cell aggregates corresponding to neoplastic follicles (Frale and Kardos, 1988). Recently, several authors proposed that grading of follicular lymphomas based on histologic criteria proposed by Mann and Berard (1983) and WHO (Jaffe et al, 2001) may be assessed in smears, based on the proportion of centroblasts in the follicular aggregates (Young et al, 1998). In our institution, **grading of follicular** lymphomas, based on centroblast counts supplemented by calculation of S-phase cells (proliferation index or PI and labelling index with Ki67 or LI, both based on image analysis of smears, correlated well with histologic grading (Sun et al, 2004).

The criteria of FL grading are summarized in Table 31-4.

Ancillary Studies

Immunophenotyping of FL is positive for B-cell-associated antigens (CD19 and CD20) and bcl-2 protein expression. Staining for CD10 is usually positive, whereas staining for CD5 and CD43 is negative.

The bcl-2 oncoprotein is expressed in approximately 80% to 90% of FLs. Expression of bcl-2 protein is helpful in differentiating reactive from neoplastic follicles on tissue sections because

bcl-2 is absent in the reactive follicles but present in most FLs. In cytologic preparations, however, bcl-2 expression is not helpful, because the architectural pattern is lost and the follicular cells are admixed with interfollicular T cells that also express this antigen (Young and Al-Saleem, 1999).

Figure 31-26 Follicular lymphoma, grade I. *A,B.* Aspirate shows small cleaved cells and rare large noncleaved cells. Note follicular aggregate (*arrow*) composed of predominantly small cleaved cells. *C.* Similarly, the tissue section shows predominantly small cleaved cells and rare large noncleaved cells. (*A:* Diff-Quik stain; *B:* Papanicolaou stains.)

DNA **ploidy analysis** of grade I FL shows a diploid population with low proliferative activity. Grade II FL usually has a diploid population but may also have a smaller aneuploid subpopulation, and it has low-to-intermediate proliferative activity. Grade III FL may have a predominantly diploid or aneuploid population with intermediate-to-high proliferative activity.

Cytogenetic studies usually show the t(14;18)(q32; 21) translocation that results in the

rearrangement of the *bcl-2* gene and in the expression of the “antiapoptosis” gene that is thought to lead to long-lived centrocytes (Tsujimoto et al, 1985; Ngan et al, 1988). The t(14;18) (q32;q21) translocation can be demonstrated on interphase nuclei in FNA specimens by using FISH (Gong et al, 2003) (Fig. 31-28).

Differential Diagnosis

Grade I FL needs to be distinguished from reactive lymphoid hyperplasia, small lymphocytic lymphoma, mantle

P.1205

cell lymphoma, and marginal zone lymphoma. Differentiating between the small-cell lymphomas has been discussed above; the key points are summarized in Table 31-5. Chhieng et al (2001) reviewed the performance of cytology supplemented by immunophenotyping in 56 cases of small-cell lymphomas of various types and organs. The correct diagnosis could be established in 46 or 82% of these cases, most of which were lymph node aspirates. In 7 cases, the evidence was insufficient for diagnosis and 3 cases were false-negative. The differential diagnosis in grades II and III FL includes peripheral T-cell lymphoma, reactive lymphoid hyperplasia with increased numbers of immunoblasts, and large B-cell lymphoma. Immunophenotyping is helpful in distinguishing among these entities.

TABLE 31-4

Group	Centroblast cell count (%) Mean	Mean PI	Mean Ki-67 LI (%)
Grade I	9.7 (5.1-15.7)	0.45 (0-1.8)	10.8 (1-25)
Grade 2	24.7 (15.9-35.5)*	1.5 (0.3-4.8)	20.4 (5-45)*
Grade 3	48.3 (37.5-60.8)*#	1.7 (1.5-3.0)*	20.8 (8-40)*

* = $p < 0.05$ vs. grade 1 group

= $p < 0.05$ vs. grade 2 group

+ Based on centroblasts within follicles counted on Papanicolaou stained directed smears

PI, proliferative Index (S-phase analysis) by image analysis; LI, labeling index with proliferation antigen Ki67

Figure 31-28 Follicular lymphoma. The cell in the center shows two fusion signals (*arrows*) indicative of the reciprocal t(14;18) translocation: one orange signal representing the *bcl-2* gene on chromosome 18, and one green signal representing the IgH gene on chromosome 14. (Interphase FISH, oil immersion.) (Courtesy of Dr. Jun Gu.)

Large B-Cell Lymphoma

Large B-cell lymphomas comprise 30% to 40% of adult non-Hodgkin lymphomas. They usually occur in the sixth decade of life, but the age range is broad and includes children and young adults. Patients typically present with a rapidly enlarging neck or retroperitoneal mass. Although large B-cell lymphomas are aggressive, they are potentially curable with multiagent, high-dose chemotherapy (Harris et al, 1994).

The tumors in this category were **formerly classified as diffuse large-cell, cleaved, noncleaved, or immunoblastic lymphoma and occasionally diffuse mixed small- and large-cell lymphoma** in the Working Formulation (Harris et al, 1994). Large B-cell lymphomas can arise de novo or be derived by transformation of a lowergrade lymphoma.

TABLE 31-5 DIFFERENTIAL DIAGNOSIS OF SMALL CELL LYMPHOMAS

Lymphoma	Immunophenotype				Cytogenetics
	CD5	CD23	CD10	CD20	
Small cell lymphocytic	+	+	-	+	Trisomy 12
Lymphoplasmacytic	-	+	-	+	No specific abnormality
Mantle cell	+	-	-	+	t(11;14)
Marginal zone	-	+/-	-	+	Trisomy 3; t(11;18)
Follicular	-	+/-	+	+	t(14;18)

Cytology

Large B-cell lymphoma is a heterogeneous group of neoplasms consisting primarily of large cleaved and noncleaved cells. In large noncleaved cell lymphoma, the cells have round to ovoid nuclei that contain one or more distinct nucleoli (Figs. 31-29 and 31-30). Large cleaved cell lymphoma, on the other hand, features **irregular nuclear profiles**, often with **nuclear protrusions (“nipples”)**. Nuclei may be vesicular with inconspicuous nucleoli. Some large B-cell lymphomas may be composed of large noncleaved cells and immunoblasts (Fig. 31-31). **Lymphoglandular bodies are usually numerous.**

Rare cases of **lymphomas with signet-ring features** have been described. These tumor cells have intracytoplasmic vacuoles that indent the nuclei (Fig. 31-32) (Limjoco et al, 1991; Yu et al, 1995; Gilcrease, 1998). The cytoplasmic vacuoles contain immunoglobulins. **These tumors may mimic metastatic adenocarcinomas;** however, the latter show the positive staining for mucin and cytokeratin that is negative in signet-ring lymphomas.

Ancillary Studies

Immunophenotyping shows positive staining for B-cell-associated antigens (CD19 and CD20). Expression of CD45 and CD10 is variable. DNA ploidy analysis usually demonstrates a diploid population with high proliferative activity (Katz et al, 1993c). Approximately 30% of cases show *bcl-2* gene rearrangement (Harris et al, 1994).

Differential Diagnosis

Large B-cell lymphoma is readily recognized as malignant tumors. It can rarely be confused with

reactive hyperplasia of lymph nodes with increased numbers of immunoblasts. However, those difficult cases can usually be resolved by immunophenotyping. Another form of lymphoma that may mimic large B-cell lymphoma is the blastic form of mantle cell lymphoma, which, however, shows CD5 positivity and rearrangements of the *bcl-1* gene.

The most important points of differential diagnosis are **metastatic small-cell carcinomas, seminomas, and melanomas** that may show a dissociated cell pattern (see below). The presence of abundant **lymphoglandular bodies** in the background of the smear tilts the diagnosis toward a lymphoma, whereas the presence of cohesive cell clusters is suggestive of an epithelial tumor. In case of doubt, positive **immunostaining for keratin supports the diagnosis of**

P.1207

carcinoma. Other points of the differential diagnosis are listed in Table 31-6. Very rarely, **granulocytic sarcoma**, composed primarily of blasts with round to oval nuclei and agranular basophilic cytoplasm, can mimic lymphoma (Fig. 31-33); however, it is positive for myeloperoxidase and naphthol AS-D chloracetate.

Figure 31-29 Large-cell lymphoma. Smear shows a monomorphous population of large

cells with numerous lymphoglandula bodies in the background. (A: Diff-Quik stain; B: Papanicolaou stain.)

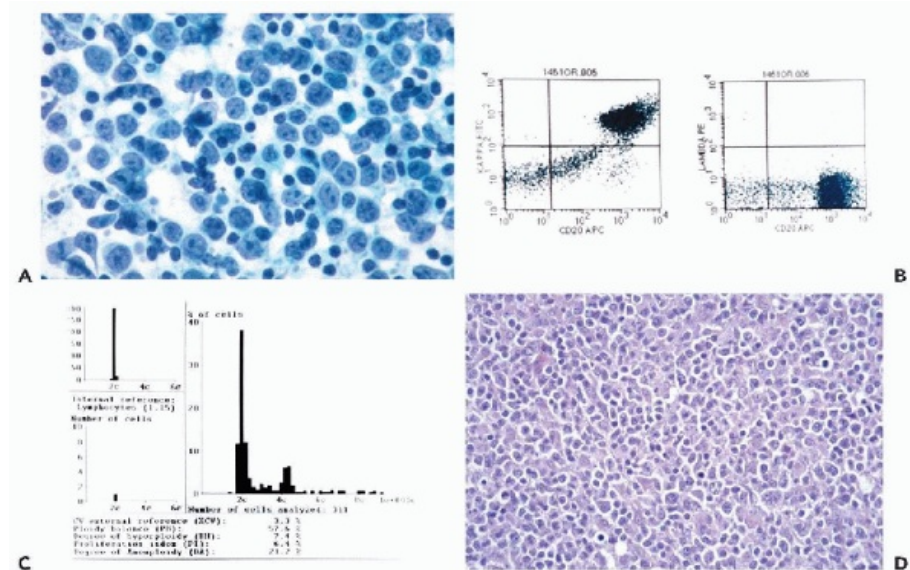

Figure 31-30 Large-cell lymphoma. A. Under high magnification, smear shows predominantly large cells with round vesicular nuclei and scattered small lymphocytes. B. Flow cytometry shows kappa light chain restriction. C. Image analysis reveals a predominantly diploid population with a high proliferation index consistent with a high-grade lymphoma. D. A monomorphic population of large cells is seen on tissue section.

Mediastinal Large B-Cell Lymphoma

The diagnosis and differential diagnosis of this distinct type of B-cell lymphoma is discussed in Chapter 37. Ancillary studies in our institution include positive **immunophenotyping** with B-cell associated antigens and a weak expression of CD 30. The tumor cells lack bcl-2 and bcl-16 arrangement.

Figure 31-31 Large-cell lymphoma with immunoblastic features. Note the large round nuclei with prominent (*arrow*) central nucleoli seen under high magnification.

Burkitt Lymphoma

Burkitt lymphoma occurs predominantly in children. Cases reported in adults are often associated with immunodeficiency. In endemic areas in Africa, the jaws and facial bones are the most commonly involved sites, whereas in nonendemic areas, the disease involves distal ileum, cecum, ovaries, retroperitoneum, kidneys, or breasts. Epstein-Barr virus (EBV) is commonly present in the endemic form of this lymphoma but rarely in the nonendemic cases. Burkitt lymphoma may sometimes mimic an acute leukemia. This tumor is highly aggressive but potentially curable. In histologic sections, Burkitt lymphoma has the typical “**starry-sky**” **pattern** caused by the large number of macrophages intermingled with lymphoma cells. Besides the “classical” pattern, a form of Burkitt lymphoma with plasmacytoid differentiation was recognized (Jaffe, 1999).

The provisional category of high-grade B-cell lymphoma, Burkitt-like, in the REAL classification was eliminated in the updated WHO classification. It was believed that this was a heterogeneous group, and that most cases could be classified either as Burkitt lymphoma or a large B-cell lymphoma (Jaffe, 1999).

Cytology

Aspirates are composed of malignant lymphocytic cells. The nuclei are spherical, with a fine to coarse chromatin

P.1208

pattern, and they contain two to five distinct nucleoli (Fig. 31-34). On air-dried Diff-Quik smears, the cells have deeply basophilic cytoplasm and prominent **cytoplasmic vacuoles** (Fig. 31-34). A “starry-sky” pattern may be present as the result of an admixture of tingible body macrophages. **Necrotic debris and mitotic figures are frequently seen** (Stastny et al, 1995).

Figure 31-32 Lymphoma with signet-ring features. Aspirate shows cells with vacuoles indenting the nucleus (*arrow*), mimicking a signet-ring adenocarcinoma. (*A*: Diff-Quik stain; *B*: Papanicolaou stain; *A,B*: oil immersion.)

Ancillary Studies

Immunophenotyping shows positivity for B-cell-associated antigens (CD19 and CD20) and CD10, and negativity for CD5 and CD23.

DNA ploidy analysis usually shows a **diploid population with very high proliferative activity**. Ki-67 expression is high; approximately 80% to 90% of cells are positive.

TABLE 31-6 DIFFERENTIAL DIAGNOSIS OF LARGE CELL TUMORS BY IMMUNOSTAINING

Tumor	LCA	Ki-1	PLAP	Keratin	HMB-45	S-100	Myelo
Large cell lymphoma	+	-	-	-	-	-	-
Seminoma	-	-	+	-	-	-	-
Carcinoma	-	-	-	+	-	-	-
Melanoma	-	-	-	-	+	+	-
Granulocytic sarcoma	+	-	-	-	-	-	+
Ki-1 lymphoma	+/-	+	-	-	-	-	-

LCA, leukocyte common antigen; PLAP, placental alkaline phosphatase; myelo, myeloperoxidase.

Cytogenetic analysis commonly shows the **translocation of *c-myc* gene from chromosome 8 to the immunoglobulin heavy chain region on chromosome 14 [t(8;14)]** and, less frequently, to the light chain loci on chromosome 2 [t(2;8)] or 22 [t(8;22)].

Differential Diagnosis

Sometimes it may be difficult to differentiate a high-grade large-cell lymphoma from Burkitt lymphoma on smears. In such cases, **cytogenetic analysis** may disclose the characteristic translocation of Burkitt lymphoma. **Lymphoblastic lymphoma** can be differentiated by its distinct **clinical manifestations** (a mediastinal mass with or without cervical lymph node involvement), its immature T-cell phenotype, and its expression of **terminal deoxynucleotidyl transferase**

P.1209

(TdT). In young patients, the **small, round-cell tumors of childhood** must also be considered in the differential diagnosis. The clinical appearance of the tumor, in conjunction with ancillary studies, such as a panel of **immunomarkers** (lymphocyte common antigen [LCA], desmin, muscle-specific actin, chromogranin, CD99, and keratin) and ultrastructural analysis may be helpful in distinguishing between these entities without performing an open biopsy (Table 31-7).

Figure 31-33 Granulocytic sarcoma. *A.* Cytospin preparation on exhibits some cells with round nuclei, whereas others have reniform nuclei. *B.* The tumor cells show positive staining for myeloperoxidase. *C.* Histologic section shows large cells with vesicular nuclei and one to two nucleoli. (*A:* Diff-Quik stain; *B:* immunoperoxidase stain; *A,B:* oil immersion.)

Plasmacytoma/Plasma Cell Myeloma

Plasmacytoma occurs in adults, **usually as a disseminated bone marrow disease (plasma cell myeloma)**, but sometimes as a solitary bone or extramedullary tumor. Involvement of the lymph nodes is rare. Although most solitary tumors involving the bone eventually develop into multiple myeloma, only 10% to 20% of extramedullary plasmacytomas progress (Harris et al, 1994).

Cytology

The tumor cells resemble mature or immature plasma cells with abundant cytoplasm with

an eccentrically located nucleus (Fig. 31-35). The nuclei are usually round with **coarsely clumped chromatin** (cartwheel arrangement of chromatin), but they may also be cleaved or resemble immunoblasts (Bangerter et al, 2000).

Figure 31-34 Burkitt lymphoma. *A.* Aspirate shows a monomorphic population of intermediate cells with round nuclei, coarse nuclear chromatin, and two or three prominent nucleoli. Note prominent apoptosis under high magnification. *B.* The presence of basophilic cytoplasm with multiple small vacuoles on air-dried smears is a helpful distinguishing feature. *C.* Tissue section shows an infiltrate of lymphocytes with scattered histiocytes resulting in a starry-sky pattern. (*B*: Diff-Quik stain, oil immersion.)

Ancillary Studies

Immunophenotyping demonstrates positive staining for cytoplasmic immunoglobulin but negative staining for surface immunoglobulin. The plasma cells usually show light chain restriction and are positive for CD38 and negative for B-cell-associated antigens (CD19 and

CD20). Staining for CD43, CD45, CD56, and epithelial membrane antigen (EMA) is variable.

Immunoglobulin heavy chains and light chains are rearranged or deleted.

Differential Diagnosis

In some cases, **lymphoplasmacytic lymphoma** and plasmacytoma may be difficult to differentiate cytologically because

P.1210

both have a plasmacytoid appearance. However, the CD20 positive lymphoplasmacytic lymphoma has a more heterogeneous cell population, in which the plasmacytoid cells are admixed with small lymphocytes. The cells of **metastatic melanoma** may also have a plasmacytoid appearance and binucleation but are easily distinguished from plasmacytoma by the presence of intranuclear inclusions, melanin pigment, and positive immunostaining for S-100 protein or HMB-45.

TABLE 31-7 DIFFERENTIAL DIAGNOSIS OF SMALL ROUND CELL TUMORS BY IMMUNOSTAINING

Tumor	MIC-2	LCA	Desmin	Keratin	Chromo
Lymphoblastic lymphoma	+	+	-	-	-
Neuroblastoma	-	-	-	-	+
Ewing's sarcoma/PNET	+	-	-	-	-
Rhabdomyosarcoma	-	-	+	-	-
DSCT	-	-	+	+	-

PNET, primitive neuroectodermal tumor; DSCT, desmoplastic small round cell tumor; LCA, leukocyte common antigen; chromo, chromogranin.

T-Cell Lymphomas

Lymphomas of T-cell lineage comprise only a small proportion of nodal lymphomas. They are **more difficult to identify on FNA than B-cell lymphomas** by routine analysis because of difficulties in detecting the clonal population of abnormal T-cells by immunophenotyping.

Polymerase chain reaction may be required to detect T-cell receptor gene rearrangement. In ambiguous cases, a biopsy may be necessary to determine tumor type.

Peripheral T-Cell Lymphoma

These neoplasms account for about half of T-cell lymphomas in the Western world. Nearly all cases occur in adults and present with nodal involvement. In the Orient, the disease can be associated with human T-cell leukemia virus (HTLV1).

Cytology

Smears exhibit a spectrum of atypical cells with nuclei varying in shape and ranging from small to large (Fig. 31-36). The small nuclei are often convoluted with condensed chromatin (Fig. 31-37), whereas the larger nuclei are round or irregular, with either vesicular or condensed chromatin. The background contains a variable admixture of neutrophils, eosinophils, plasma cells, and epithelioid and nonepithelioid histiocytes. In some cases, **bizarre or pleomorphic cells**, some even resembling Reed-Sternberg cells, can be seen (Katz et al, 1989; Young and Al-Saleem, 1999; Galindo et al, 2000).

Ancillary Studies

Immunophenotyping is helpful in diagnosing peripheral T-cell lymphomas in order to document the T-cell lineage and an aberrant T-cell phenotype (Table 31-8). **At least one of the pan-T-cell markers (CD2, CD3, CD5, or CD7) should be positive, whereas B-cell markers are negative.** Demonstrating the absence of B-cell antigens is important because some B-cell lymphomas can coexpress T-cell antigens. In addition, peripheral T-cell lymphomas often express an aberrant T-cell phenotype with loss of one or more of the pan-T-cell markers (Young and Al-Saleem, 1999) and expression of (gamma, delta) T-cell receptor.

DNA ploidy analysis usually shows a **diploid population with intermediate proliferative activity.**

Approximately **80% to 90% of T-cell lymphomas have rearrangements of the T-cell receptor genes.** Therefore, in difficult cases, molecular studies (PCR) may be helpful to demonstrate these gene rearrangements, although their absence does not exclude T-cell lymphoma (Weiss et al, 1988).

Differential Diagnosis

A diagnosis of peripheral T-cell lymphoma by FNA may be difficult because of a mixed population of cells that is also present in **reactive processes**. When pleomorphic or bizarre cells are present, the differential diagnosis should include **Hodgkin lymphoma, various B-cell lymphomas, and a variety of metastatic tumors.** Knowledge of the patient's clinical history and presentation is essential in the evaluation.

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides and Sézary syndrome are two different manifestations of the same or similar disorder, having in common the presence of abnormal T-helper cells with **characteristic cerebriform configuration of nuclei** (Knobler and Edelson, 1986; Barcos, 1993; Berti et al, 1999). Both forms of the disease involve the skin: mycosis fungoides begins with areas of redness (erythema) that evolve into plaques and palpable tumors; Sézary syndrome shows diffuse erythema and some features of **leukemia**—the presence of the abnormal lymphocytes in circulating blood (Van Doorn et al, 2000).

P.1211

Although, as the name indicates, cutaneous T-cell lymphoma is primarily a disease of the skin, **involvement of other organs, mainly lymph nodes** is a common event particularly in the late stages of the disease (Scheffer et al, 1986; Vonderheid et al, 1992, 1994; van Doorn et al, 2000). Other organs, such as **the central nervous system, lung, esophagus, orbit, and breast may be involved by the disease** (Rosen et al, 1984; Schwartz and Clark, 1988; Redleaf et al, 1993; Zucker and Doyle, 1991). **Association with Hodgkin lymphoma** has

been reported on several occasions (recent review in Bee et al, 2001).

Figure 31-35 Plasmacytoma. *A,B.* Smears show a dispersed population of cells with abundant basophilic cytoplasm, eccentrically located nuclei, and prominent nucleoli. *C.* Immunocytochemical studies show monoclonal staining for kappa as well as CD38 positivity indicative of plasma cell differentiation. Proliferation index (Ki67) is elevated. (*A:* Diff-Quik stain; *B:* Papanicolaou stain; *C:* immunoperoxidase stain; *A,B:* high magnification.)

Figure 31-36 Peripheral T-cell lymphoma. A heterogeneous lymphoid population is present. Note the small- to intermediate-size angulated lymphoid cells and larger transformed cells. (*A*: Diff-Quik stain; *B*: Papanicolaou stain; *A,B*: high magnification.)

The **prognosis and length of survival are stage related**: disease confined to the skin (stage I) has a better prognosis than disease with benign (dermatopathic) lymph node enlargement (stage II), metastatic spread to lymph nodes (stage III) or viscera (stage IV) (van Doorn et al, 2000). Patients in stages III and IV have limited survival.

Figure 31-37 Peripheral T-cell lymphoma. Smears show predominantly small cells with cleaved or angulated nuclei.

P.1212

TABLE 31-8 IMMUNOPHENOTYPING TO DIFFERENTIATE BETWEEN CLASSIC HODGKIN LYMPHOMA AND ANAPLASTIC LARGE CELL LYMPHOMA

	Classic H2	Anaplastic Lymphoma
CD15	+	-
CD30	+	+
CD45	-	+
EMA	-	+/-
ALK	-	+

EMA, epithelial membrane antigen; ALK, anaplastic lymphomay kinase.

Cytology

Cytologic evaluation of lymph nodes in cutaneous T-cell lymphoma is not only a matter of idle curiosity but it has prognostic value (Vonderheid et al, 1992). In **fixed smears** stained with Papanicolaou, the abnormal lymphocytes have irregularly shaped nuclei showing peripheral indentations and large nucleoli. The **peculiar small lymphocytes with longitudinally**

grooved, cerebriform configuration of chromatin are much better seen in air-dried smears, stained with one of the hematologic stains (Fig. 31-38). Vonderheid et al (1992) observed in histologic material that patients with the presence of small atypical "cerebriform" lymphocytes in lymph nodes had a better survival than patients whose lymph nodes contained larger, more abnormal cells. This observation was confirmed in aspirated material by Galindo et al (2000), who reported, however, that the cell type had limited prognostic significance but offered good correlation with histology. There is published evidence that the abnormal lymphocytes may be recognized in cytologic preparations from various organs such as the sputum, cerebrospinal fluid, soft tissue masses (Rosen et al, 1984; Shaheen and Oertel, 1984); Schwartz and Clark, 1988; Zucker and Doyle, 1991; Redleaf et al, 1993; Laforga et al, 1998). Also see respective chapters.

Figure 31-38 Mycosis fungoides metastatic to a lymph node. Composite photograph of a lymph node aspirate. *A.* Alcohol fixed and Papanicolaou-stained smear. The smear shows bizarre, irregular nuclei with cerebriform pattern of chromatin, characteristic of this disorder. *B.* Positive stain with an antibody to T cells. (Case courtesy Dr. Britt-Marie Ljung, San Francisco, Calif.)

Ancillary Studies

T-cell deletion and T-cell receptor and T-cell receptor gene rearrangement studies are diagnostically helpful (Ormsby et al, 2001). The presence of T-cell antigen receptor gene is useful in differentiating dermatopathic adenopathy from lymph nodes involved by tumor cells (Lynch et al, 1992). CD-4 helper cells phenotype is also expressed in tumor cells. Berti et al (1999) reported that rare patients with CD8 positive cells had a bad prognosis.

Differential Diagnosis

An erroneous diagnosis of **Hodgkin lymphoma** of lymph nodes was reported in an exceptional patient in whom the classical manifestations of skin involvement were absent (Schwartz and Clark, 1988). Such errors are avoidable based on unique morphology of cancer cells and knowledge of clinical history. Perhaps the most important point of differential diagnosis is **dermatopathic lymphadenopathy**, discussed above, a benign entity that may also occur in mycosis fungoides (Burke et al, 1986; Asano et al, 1987). The presence of atypical dendritic cells, common in dermatopathic lymphadenopathy, may lead to an erroneous diagnosis of T-cell lymphoma. A study of immune markers is required in difficult cases.

Lymphoblastic Lymphoma

Lymphoblastic lymphoma occurs predominantly in adolescents and young adult men but it can occur in all age groups. The first manifestation of disease is usually a **mediastinal mass**. The disease progresses rapidly to involve the peripheral blood, bone marrow, central nervous system, and gonads. The tumor is potentially curable with proper therapy but fatal if untreated.

Lymphoblastic lymphoma is composed

P.1213

of immature lymphoid cells, usually of T-cell origin, although they can be of B-cell derivation. Therefore lymphoblastic lymphoma is listed under both subtypes and is designated as a **precursor of lymphoblastic leukemia/lymphoma** (Harris et al, 1994) (see Table 31-3).

Cytology

Aspirates taken from patients with lymphoblastic lymphoma show a monomorphous population of lymphoid cells of intermediate size with nuclei that may be lobulated, convoluted, or, less often, round or oval. The chromatin is finely granular or opaque, and the nucleoli are inconspicuous (Fig. 31-39). The presence of these features, along with the presence of **numerous mitotic figures**, helps to exclude low-grade lymphoma from the diagnosis. No cytologic distinction can be made between tumors of B-cell and T-cell lineages (Jacobs et al, 1992).

Ancillary Studies

Most lymphoblastic lymphomas are of T-cell origin and have variable phenotypic markers (CD1, CD2, CD3, CD4, CD5) that are also seen with cortical thymocytes. In most cases, the cells are positive for CD3 and CD7 and may be positive or negative for CD4 and CD8. **Cells are characteristically positive for TdT, which is the single most helpful marker.** Cells are variably positive for CD10 (CALLA). Approximately 30% of these tumors express pan-B-cell markers (CD19 and CD20) (Young and Al-Saleem, 1999).

DNA ploidy analysis usually shows **a diploid population with intermediate-to-high proliferative activity** (Ki-67 expression is high).

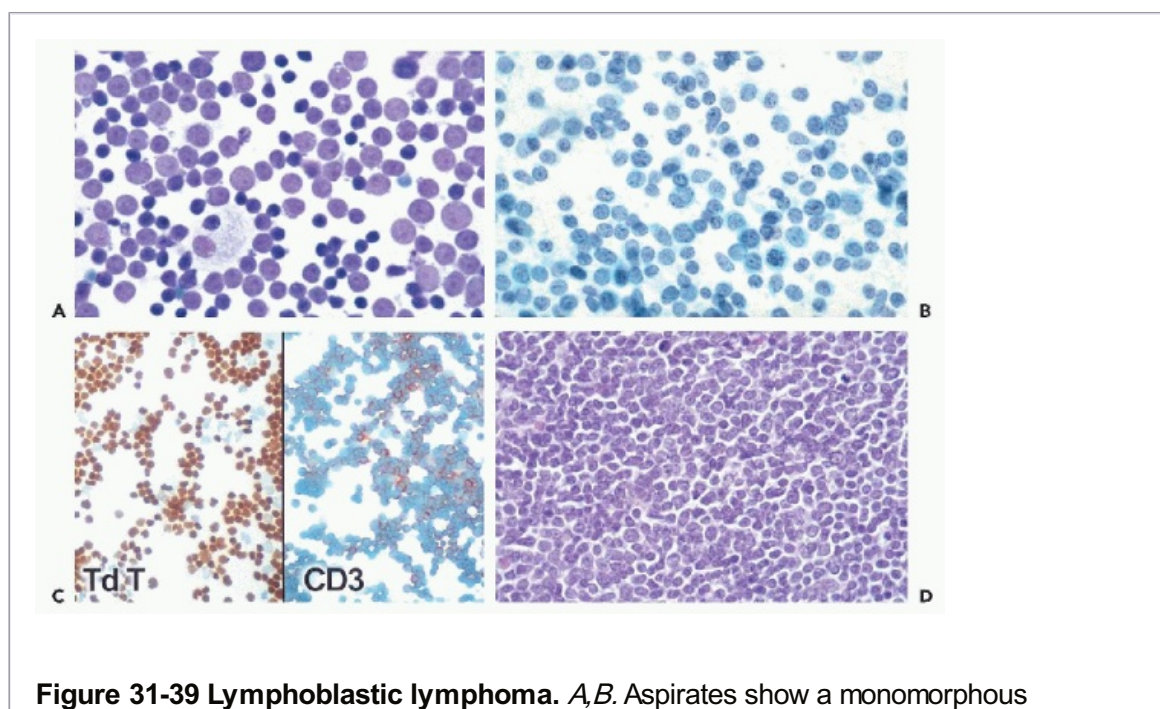

Figure 31-39 Lymphoblastic lymphoma. A,B. Aspirates show a monomorphous

population of cells with fine nuclear chromatin, best seen on air-dried smears. *C.* Tumor cells show positive staining for TdT and CD3, T cell marker. *D.* Tissue shows a diffuse infiltrate of cells with scant cytoplasm. (*A:* Diff-Quik stain; *B:* Papanicolaou stain; *C:* immunoperoxidase stain; *A,B:* high magnification.)

Rearrangements of the T-cell receptor and immunoglobulin heavy chain genes are variable (Harris et al, 1994).

Differential Diagnosis

Granulocytic sarcoma can be differentiated from lymphoblastic lymphoma by its positive staining with myeloperoxidase, naphthol AS-D chloroacetate, and Sudan black. The nuclei in **Burkitt lymphoma** have coarse nuclear chromatin and the cells are negative for TdT.

Aspirates from the mediastinum should be interpreted with caution, because **lymphocytes from a lymphocyte predominant thymoma can show a similar phenotype to those in lymphoblastic lymphoma, including positivity for TdT**. However, lymphocytes from thymoma are usually mature, whereas those from lymphoblastic lymphomas have fine nuclear chromatin (Friedman et al, 1996). In addition, the age of the patient is helpful—thymomas usually occur in individuals older than 50 years, whereas lymphoblastic lymphoma usually occurs in the second and third decades of life. For further discussion of thymomas, see Chapter 37.

Anaplastic Large-Cell Lymphoma

Anaplastic large-cell lymphoma is a distinct entity that has a T-cell or null-cell phenotype, as defined by the REAL classification; B-cell tumors formerly in this category are now included in the large B-cell category (Harris et al, 1994). There is evidence that there are two distinct forms of anaplastic large cell lymphoma—a **systemic form**, which

P.1214

may involve lymph nodes and extranodal sites (with or without skin involvement), and a **cutaneous form**, which affects only the skin. The cutaneous form will not be discussed in this chapter because it is usually not amenable to FNA. The systemic form has a bimodal age distribution, occurring in children and adults (Chott et al, 1990; Penny et al, 1991). It is clinically aggressive, but it may respond to aggressive therapy. A **neutrophil-rich** form of this group of diseases was described (Mann et al, 1995).

Cytology

Most commonly, **aspirates contain large cells with pleomorphic, hyperchromatic nuclei and abundant cytoplasm, often mimicking epithelial cancer cells**. Small cell and lymphohistiocytic variants have also been described. In the pleomorphic type, the nuclei can be multilobulated, horseshoe-shaped, bagel-shaped, or multiple and contain one or more prominent nucleoli (Fig. 31-40). The multinucleated forms may resemble Reed-Sternberg cells (Kadin et al, 1994). The **neutrophil-rich form may mimic an abscess** because of abundance of polymorphonuclear leukocytes (Mann et al, 1995; Creager et al, 2002).

Ancillary Studies

Anaplastic large-cell lymphomas characteristically show **strong paranuclear staining for CD30 (Ki-1 antibody)** (Fig. 31-40), but only 67% are positive for CD45 (lymphocyte common

antigen or LCA) (Weiss et al, 1993). Staining for T-cell-associated antigens is variable. Tumor cells in the systemic form are often positive for epithelial membrane antigen (EMA) and anaplastic lymphoma kinase (ALK1).

Figure 31-40 Anaplastic large cell lymphoma. *A,B.* Smears show a dispersed population of pleomorphic tumor cells. *C,D.* The tumor cells on the left show dot-like staining for CD30 (Ki-1), while on the right Ki-67 is positive in the majority of cells indicative of a high-grade lymphoma. (*A:* Diff-Quik stain; *B:* Papanicolaou stain; *C,D:* Immunoperoxidase stain; *A,B:* oil immersion).

DNA ploidy analysis may show a diploid or aneuploid population with high proliferative activity. Ki-67 expression is usually very high, with more than 60% of positive cells.

A t(2;5)(p23;q35) translocation occurs in about 67% of anaplastic large-cell lymphomas. As a result, the anaplastic lymphoma kinase (ALK) gene on chromosome 2 fuses with the nucleophosmin (NPM) gene on chromosome 5 (Wellman et al, 1995; Falini et al, 1999). The t(2;5) translocation has been documented in FNA specimens by FISH technique (Thorson et al, 2000). The chimeric **protein product of the translocation**, known as **p80**, may be documented in more than half the cases by immunocytologic reaction with a commercially available antibody (Kinney and Kadin, 1999).

Differential Diagnosis

It is important to differentiate anaplastic large-cell lymphoma from poorly differentiated metastatic carcinoma because of major differences in prognosis, which is poor in metastatic disease, whereas anaplastic lymphoma has a very high response rate to therapy (McCluggage et al, 1996; Jarayam and Abdul Rahman, 1997). Knowledge of the clinical setting may not be sufficient because both diseases occur among the elderly.

To complicate the issue still further, not all anaplastic lymphomas express CD45 (lymphocytic common antigen) and, thus, a **panel of immunostains** must be applied to poorly differentiated neoplasms. Anaplastic lymphoma is characterized by the high expression of CD30 in most cancer cells, in contrast to some other lymphomas, which show only focal staining (Penny et al,

1991). Both carcinomas

P.1215

and anaplastic lymphomas are positive for EMA but the lymphoma is **negative for keratin**. A noteworthy point is that **metastatic embryonal carcinomas** may be positive for both CD30 and keratin but they have distinct morphologic features in the form of cohesive cell clusters that do not occur in lymphomas. Melanomas, if suspected, are positive for S-100 protein and HMB-45.

Smears of anaplastic large-cell lymphoma may contain **Reed-Sternberg-like cells** that are impossible to distinguish from such cells in Hodgkin lymphoma (Tani et al, 1989; Aljajeh et al, 1995). The Reed-Sternberg cells in Hodgkin lymphoma, however, are positive for both CD30 and CD15 (Leu-M1), whereas the similar cells in anaplastic large-cell lymphoma are negative for CD15 (see Table 31-8). Further, the CD30 response in Hodgkin lymphoma is limited to Reed-Sternberg cells, whereas in anaplastic large-cell lymphoma, most cells express this antigen. The presence of the t(2;5) translocation in anaplastic large-cell lymphoma or positive immunostaining for the product of ALK gene fusion may also be helpful in distinguishing between these two diseases. Patients whose cells have positive expression of ALK by immunocytochemistry have also been shown to have a more favorable therapeutic outcome (Kadin and Morris, 1998).

Hodgkin Lymphoma

Hodgkin lymphoma accounts for approximately 20% of newly diagnosed lymphomas. The updated WHO classification lists two distinct types of Hodgkin's lymphoma—**classic and nodular lymphocyte-predominant**. Classic Hodgkin lymphoma is further subdivided into **nodular sclerosis, lymphocyte-rich, mixed cellularity, and lymphocytic depletion types**. The nodular lymphocyte-predominant type is now recognized as a distinct entity that is both clinically and phenotypically different from classic Hodgkin lymphoma (Jaffe et al, 1999).

FNA has an important but limited role in the initial diagnosis of Hodgkin lymphoma (Young and Al-Saleem, 1999). If the cytomorphologic features and immunophenotypic findings are suggestive of a diagnosis of Hodgkin lymphoma, then a tissue biopsy is recommended for confirmation and subclassification. However, FNA is **very useful in diagnosing recurrent disease** (Das et al, 1990a; Das and Gupta, 1990b).

Cytology

The cytologic diagnosis of Hodgkin lymphoma mainly is made on the basis of the presence of classic Reed-Sternberg cells in a background of lymphocytes, plasma cells, eosinophils, and histiocytes. Classic Reed-Sternberg cells are large binucleated or multinucleated cells with pale abundant cytoplasm that contain nuclei with reticulated chromatin and prominent macronucleoli (Fig. 31-41). The nucleus often appears surrounded by a clear, empty cytoplasmic halo. Instead of classic Reed-Sternberg cells some aspirates contain **Hodgkin cells**, which are large mononuclear cells with reticulated chromatin and one or two prominent nucleoli (Fig. 31-42). Although these cells are not fully diagnostic, they are suggestive of Hodgkin lymphoma in the proper clinical setting.

Figure 31-41 Hodgkin lymphoma. *A,B.* A classic Reed-Sternberg cell (*arrow*) is present in a background of lymphocytes and rare eosinophils. *C.* Histologic section shows lacunar cells and a diagnostic Reed-Sternberg cell (*arrow*). (*A:* Diff-Quik stain; *B:* Papanicolaou stain; *A,B:* oil immersion; *C:* high magnification.) (*A,B:* Courtesy of Dr. Koss.)

Although some investigators (Das et al, 1990; Das and Gupta, 1990) have subtyped Hodgkin lymphoma according to the relative proportions of neoplastic cells (Hodgkin's and Reed-Sternberg cells) and reactive cellular components on cytologic preparations, this is not done routinely at our institution. However, one should be aware of the spectrum of cytologic features seen in the different subtypes of Hodgkin lymphoma.

Aspirates from lymph nodes of patients with **nodular, sclerosing Hodgkin lymphoma**, the most common subtype, usually contain classic Reed-Sternberg cells, lacunar cells, eosinophils, lymphocytes, and histiocytes. **Lacunar cells** are large cells with abundant clear or pale cytoplasm that contain indented or overlapping segmented nuclei; these cells are not specific for Hodgkin lymphoma. The **mixed cellularity subtype of Hodgkin lymphoma** has cells very

similar to those of the nodular sclerosis subtype, except for the absence of lacunar cells.

P.1216

Figure 31-42 Hodgkin lymphoma. Typical mononucleated cells, binucleated cells and large cells with hyperlobulated nuclei (L and H or popcorn cells) are present in a background of lymphocytes. The “popcorn” cells have pale nuclei and visible nucleoli (*arrows*). The “popcorn” cells are usually observed in the nodular, lymphocyte-predominant subtype of Hodgkin lymphoma. (Diff-Quik stain, high magnification.) (Courtesy of Dr. Koss.)

In the **lymphocytic depletion subtype** of Hodgkin lymphoma, aspirates are often sparsely cellular consisting of Reed-Sternberg and Hodgkin cells in a background of lymphocytes or fibroblasts.

The **nodular lymphocyte-predominant subtype** of Hodgkin lymphoma may be suggested by cytologic preparations that have epithelioid histiocytes and the polyploid variant of Reed-Sternberg or the so called L and H cells in a background of mature lymphocytes. The term L and H refers to “lymphocytic and histiocytic” form of Hodgkin lymphoma. The L&H cells appear as multinucleated cells with overlapping pale nuclei with central nucleoli, also known as “**popcorn cells**” (Fig. 31-42). Classic Reed-Sternberg cells are very rarely found in such cases.

Ancillary Studies

Most Reed-Sternberg cells and their variants are positive for CD15 and CD30 except for those in nodular lymphocyte-predominant Hodgkin lymphoma, and are negative for CD45 and EMA (Table 31-9). They are usually negative for B-cell and T-cell markers. The lymphocytes in Hodgkin lymphoma are nonneoplastic and have a T-cell origin.

TABLE 31-9 THE USE OF IMMUNOPHENOTYPING TO DIFFERENTIATE BETWEEN CLASSIC AND NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

	Classic HD	LPHD
CD15	+/-	-
CD30	+	-
CD45	-	+
EMA	-	+
CD20	-	+
CD3	-	-
EMA, epithelial membrane antigen.		

In nodular lymphocyte-predominant Hodgkin lymphoma, the L&H (“popcorn”) cells are of B-cell lineage. They are positive for CD20, CD45, and EMA, but negative for immunoglobulin light chains and CD15. They may be positive or negative for CD30.

Differential Diagnosis

Large, binucleated cells resembling Reed-Sternberg cells have been described in both benign and malignant diseases (Table 31-10). **Aspirates from lymph nodes of patients with reactive hyperplasia associated with infectious mononucleosis, postvaccinal lymphadenitis, and hypersensitivity to phenytoin may contain atypical immunoblasts that resemble Reed-Sternberg cells and their mononuclear variants.** These cells however usually have coarser chromatin and **much smaller nucleoli** than those in Hodgkin lymphoma (Kardos et al, 1986; Stanley et al, 1990b). Also, EBV-infected lymph nodes contain a spectrum of transformed lymphocytes, including immunoblasts that may mimic Hodgkin cells. Small lymphocytic lymphoma can be differentiated from the nodular lymphocyte-predominant subtype of Hodgkin lymphoma by the presence of paraimmunoblasts and the lack of L&H cells. Aspirates from the lymph nodes of patients with **anaplastic large-cell lymphoma** may contain atypical mononuclear cells resembling Reed-Sternberg variants in a background of small T-cells, making differentiation from Hodgkin lymphoma difficult. Although both Hodgkin lymphoma and anaplastic large-cell lymphoma are positive for CD30, only the latter is positive for ALK1. In some cases, **studies of gene rearrangements** may be helpful, because anaplastic large-cell lymphoma has rearrangements of the T-cell-receptor gene and, in many cases, the t(2;5) translocation. **Poorly differentiated carcinoma and melanoma** (Fig. 31-43) may also be considered in the differential diagnosis. Positive immunostaining for keratin confirms the former, whereas positivity for S-100 protein and HMB-45 confirms the latter. In a remarkably candid account, Jiménez-Heffernan et al (2001) acknowledged that in Hodgkin lymphoma, **diagnostic errors in the form of either false-positive or false-negative results are common and that an accurate diagnosis requires a great deal of experience.**

METASTATIC TUMORS IN LYMPH NODES

Metastatic cancer is a far more common cause of enlarged peripheral lymph nodes than malignant lymphoma, especially in patients older than 50 years. Our experience has been that FNA is a reliable method of diagnosing metastatic cancer, a task that is much easier than diagnosing lymphomas. Berg (1961) identified the circumstances that facilitate the diagnosis of lymph node metastases by FNA.

- **Enlarged peripheral lymph nodes** that are usually accessible to palpation and aspiration.
- **Aspirates of lymph nodes** affected by metastatic tumors are usually rich in tumor cells.
- **Cancer cells** of epithelial origin and those from melanomas can easily be distinguished from cells of lymphoid origin.
- **Cancer cells** in smears can often be compared with a tissue section of the primary tumor.

Aspirates serve to not only establish the diagnosis of a metastatic tumor, but to also usually

permit a definition of the histologic type and sometimes the organ of origin (Table 31-11) of the metastasis (Koss et al, 1992).

Squamous Carcinoma

The cytologic appearance of squamous carcinoma depends on the degree of differentiation by the tumor. **Keratinizing cancers** are readily identified when cells with abundant, **sharply demarcated, dense, eosinophilic cytoplasm and pyknotic nuclei** are present in smears. Anucleated squames may also appear, as may spindle-shaped and tadpole-shaped cells, arranged in a cell-within-cell (bird's-eye or "squamous pearl") pattern (Koss et al, 1992). Occasionally, aspirates from lymph nodes containing metastases of well-differentiated squamous carcinomas consist **exclusively of keratin-forming cells** with small pyknotic nuclei and without the typical features of cancer cells (Fig. 31-44). **When such smears are obtained from lesions located in the lateral**

P.1218

aspect of the neck, a branchial cleft cyst must be considered in the differential diagnosis (Koss et al, 1992). **Pilomatrixoma** is another consideration, especially in young patients; however, these are superficial subcutaneous lesions, usually in the head and neck area (Woyke et al, 1982; Gomez-Aracil et al, 1990).

Figure 31-44 Metastatic keratinizing squamous carcinoma. Atypical keratinizing cells are present in this neck aspirate from a patient with laryngeal carcinoma.

Nonkeratinizing squamous carcinomas or **epidermoid carcinomas** are represented by round, oval, or polygonal cells with sharply demarcated pale cytoplasm and coarsely granular nuclear chromatin. The precise subclassification of nonkeratinizing squamous carcinomas may be considerably more difficult than the well-differentiated keratinizing tumors. **The cytologic features may overlap those of poorly differentiated adenocarcinoma.** In addition, carcinomas that contain both squamous and glandular differentiation may occur; these are most often of bronchogenic origin.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is subtyped as keratinizing squamous carcinoma (type 1), nonkeratinizing carcinoma (type 2), and undifferentiated carcinoma, also known as **lymphoepithelioma** or **Schimke tumor** (see Chap. 21). It is a common tumor in Asians, affects men more commonly than women, and has a bimodal age distribution with peaks in the second and sixth decades. **Cervical lymphadenopathy may be the first manifestation of this disease,** although nasal discharge or epistaxis, and middle ear symptoms may be noted. EBV has been associated with this neoplasm. The documentation of the presence of EBV in lymph node aspirates is helpful in establishing the diagnosis (see Chap. 21). Very rarely, **adenocarcinomas of colonic type** may occur in the nasopharynx.

Aspirates of nasopharyngeal carcinoma show epithelial tumor cells arranged **in dense clusters or occurring singly**, with **variable numbers of lymphocytes in the background.** The keratinizing tumors seldom pose diagnostic difficulties; however, the **undifferentiated (lymphoepithelioma) subtype can be misinterpreted as lymphoma.** In undifferentiated nasopharyngeal carcinoma, the nuclei of epithelial cells are hyperchromatic and oval- to spindle-shaped with irregular nuclear borders. One to two prominent central nucleoli are often present. The cells are often stripped of their cytoplasm, but when it is present, it is thin and wispy (Grenko and Shabb, 1991). In most cases, the lymphocytes are normal.

The **differential diagnosis** of metastatic undifferentiated nasopharyngeal carcinoma includes **malignant lymphomas** and **metastatic carcinomas** from other primary sites. The larger cancer cells may mimic Hodgkin cells and Reed-Sternberg cells seen in **Hodgkin lymphoma** or the cells seen in large cell lymphoma. Positive staining of tumor cells for keratin excludes lymphoma.

Adenocarcinoma

Aspirates from the lymph nodes of patients with metastatic adenocarcinomas, regardless of the site of origin, usually contain tumor cells that are arranged singly or in cohesive groups (Fig. 31-45) of various sizes (Koss et al, 1992). The cell groups may consist of **ball-like clusters**, **papillary fragments**, **loose clusters**, or **acini with central lumina.** The tumor cells may be round, cuboidal, or columnar. The appearance of the cytoplasm may vary from homogeneous to markedly vacuolated: the vacuoles may be small and numerous or large, causing margination and indentation of the nucleus. Left supraclavicular lymph node (**Virchow node**) may be the site of metastases of gastrointestinal tumors.

Figure 31-45 Metastatic adenocarcinoma. Smear shows cohesive groups of cells with round to oval nuclei and prominent nucleoli.

Some metastatic adenocarcinomas have cytologic features that give clues to their site of origin.

Large signet-ring cells (Fig. 31-46) with intracytoplasmic mucin are commonly associated with gastric carcinomas, although they may be seen in other primary tumors. **Columnar cancer cells with elongated, palisading nuclei in a background of necrotic debris suggest a colonic primary tumor** (Fig. 31-47). Immunostaining for keratin 20 and keratin 7 may be helpful in determining the origin of some metastatic tumors (Table 31-12). Mucicarmin staining is helpful in demonstrating intracytoplasmic mucin in cytologic preparations and can be performed on destained Papanicolaou-stained smears. **In general, the presence of intracytoplasmic mucin excludes hepatocellular, renal,**

P.1219

adrenal, or thyroid carcinomas. Positive expression of the thyroid transcription factor 1 (TTF-1) is occasionally helpful in the identification of bronchogenic carcinoma (Lau et al, 2002).

Figure 31-46 Metastatic gastric adenocarcinoma with signetring features. Tumor cells contain vacuoles indenting the nucleus. (Diff-Quik stain, high magnification.)

Figure 31-47 Metastatic adenocarcinoma consistent with colonic primary. Smears show tumor cells with elongated palisading nuclei in a background of necrosis. Note the gland formation.

Renal cell carcinoma can metastasize many years after the initial diagnosis of the primary tumor is made. The cells of this tumor are usually arranged in monolayered sheets of various sizes, have abundant clear cytoplasm, often with well-defined cytoplasmic borders, and round nuclei with prominent nucleoli. The **spindle cell variant of renal cell carcinoma may imitate spindle cell sarcoma** (Koss et al, 1992). The tumor cells are **positive for keratin and vimentin**, facilitating their recognition (see Chap. 40).

In men, glandular cells, arranged in a cribriform pattern with round nuclei and prominent nucleoli (Fig. 31-48) or occurring in small clusters, are suggestive of a prostatic primary tumor. Butler et al (1971) described supraclavicular metastases as the initial manifestation of prostatic carcinoma in some patients. Positive immunostaining for **prostate-specific antigen** or **prostatic acid phosphatase** supports this diagnosis.

TABLE 31-12 USE OF CYTOKERATINS 7 AND 20 IN DETERMINING ORIGIN OF METASTATIC CARCINOMA

CK7	CK20	Carcinoma
		Non-small cell carcinoma of lung
		Bronchoalveolar carcinoma of lung

		Urothelial carcinoma
+	+	Pancreatic carcinoma
		Ovarian mucinous carcinoma
		Hepatocellular carcinoma
		Renal cell carcinoma
-	-	Adrenal carcinoma
		Squamous carcinoma of lung
		Small cell carcinoma of lung

From Weng et al, 1995 with permission.

Thyroid papillary carcinomas often metastasize to the lymph nodes of the neck. Smears from aspirates may show papillary fragments, monolayered sheets, syncytial groups, and/or single cells. The **nuclei** are often oval-shaped and have fine, powdery chromatin, **intranuclear cytoplasmic inclusions**, **intranuclear grooves**, and small nucleoli (Fig. 31-49). The

cytoplasm is usually dense and well defined. **Psammoma bodies alone**, even if not accompanied by cells observed in an aspirate from a neck lymph node, are suggestive of metastatic thyroid carcinoma. However, **psammoma bodies** may also occur in metastases from the lung or endometrium and may be numerous in metastatic ovarian carcinoma. Metastatic well-differentiated thyroid follicular carcinomas show small clusters of epithelial cells arranged in rosette-like structures. The nuclei are often round with fine, granular chromatin and small nucleoli. The **presence of colloid** is a helpful distinguishing characteristic. These tumors show positive immunostaining with thyroglobulin and thyroid transcription factor-1 (TTF-1) (Lau et al, 2002).

Metastatic breast carcinoma should be one of the diagnoses considered when evaluating axillary lymph node aspirates from women, especially those older than 50 years. Aspirates from the nodes of patients with metastatic ductal carcinoma show cancer cells singly, in cohesive groups, or both (Fig. 31-50). The tumor cells in **metastatic lobular carcinoma** (Fig. 31-51) are usually smaller than those seen in the ductal type; they can occur singly, in small clusters, and sometimes in single file. The characteristic feature of these tumors is the presence of **miniature signetring cells** that have a condensation of mucin within the vacuoles. These cells stain strongly positive for mucin and have been named “**magenta cells**” in MGG-stained smears. Cytologic techniques have also been used for demonstration of micrometastases (see Chap. 29).

When evaluating lymph node aspirates for metastatic disease,

P.1220

one should also keep in mind that more than one process may involve the lymph nodes. In rare cases, lymph node aspirates have revealed the presence of both metastatic carcinoma and lymphoma (Fig. 31-52) (Caraway et al, 1997). The lymphomas in these cases are usually low grade and are easily overlooked (see also Chap. 26).

Figure 31-48 Metastatic prostate adenocarcinoma. The gland-forming tumor cells have round nuclei with prominent nucleoli.

Figure 31-49 Metastatic papillary carcinoma of the thyroid. *A.* The nuclei have fine chromatin, nuclear grooves, intranuclear inclusions, and micronucleoli. *B, C.* Histologic section shows papillary groups. Note the clearing of the nuclei on high power (*C*).

Small-Cell Carcinoma

Small-cell carcinoma most often arises in the **lung**, but it also can be observed in other primary sites such as the **prostate, urinary bladder, larynx, paranasal sinuses, cervix, and skin** (e.g, **Merkel cell carcinoma**). Aspirates from the lymph nodes of patients with metastatic small-cell carcinoma usually contain small cancer cells occurring singly and in loosely cohesive groups. The tumor cells are two to three times larger than mature lymphocytes and have only a small rim of cytoplasm. The nuclear chromatin is finely granular but the nuclei can be hyperchromatic and, at times, pyknotic (Fig. 31-53). Nucleoli are inconspicuous or absent. **The presence of aggregates of tumor cells with nuclear molding and extensive necrosis is characteristic of small-cell carcinoma** (Shin and Caraway, 1998). **The necrotic material derived from crushed nuclei may appear in the form of “blue streaks” of DNA in the**

background of the smear.

Figure 31-50 Metastatic breast carcinoma. A cohesive group of large cells with round nuclei and prominent nucleoli is present in a background of small lymphocytes consistent with metastatic high-grade ductal carcinoma. (*A*: Diff-Quik stain; *B*: Papanicolaou stain.)

At times, it can be difficult to distinguish small-cell carcinoma from lymphoma because of cellular distortion or artifacts from air-drying of the smears. Immunostaining may be helpful in the diagnosis because small-cell carcinoma is

P.1221

focally positive for keratin and negative for lymphocyte common antigen (LCA).

Figure 31-51 Metastatic breast carcinoma. Smear shows scattered single cells that are relatively small consistent with metastatic lobular carcinoma.

Figure 31-52 Breast carcinoma metastatic to lymph node involved by small lymphocytic lymphoma. *A* Aspirate of axillary lymph node shows large atypical cells in a background of small lymphocytes with clumped chromatin. *B*. The large atypical cells are positive for keratin. (Immunoperoxidase stain.)

Figure 31-53 Metastatic small cell carcinoma. Aspirate shows both cohesive groups of cells and single cells with fine nuclear chromatin. Nuclear molding and apoptotic bodies are also noted (*A*: Diff-Quik stain; *B*: Papanicolaou stain.)

In **Merkel cell carcinoma**, keratin stain typically shows **paranuclear “dot-like” staining** that corresponds to **aggregates of intermediate filaments** (see Chap. 34).

Germ Cell Tumors

Germ cells tumors occur more frequently in men than in women and have a peak incidence in the second and third decade. Although these tumors usually arise from **the testes and ovaries**, they occasionally develop in extragonadal sites, usually located along the midline, such as the **mediastinum, retroperitoneum, sacrococcygeal area, and pineal body**. These tumors may metastasize to regional lymph nodes, most commonly those in the **retroperitoneum**. For clinical management, it is helpful to differentiate **seminoma** from **nonseminomatous germ cell tumors**.

Aspirates of the lymph nodes from patients with **seminoma** show a predominantly dispersed population of **large cancer cells** admixed with small mature **lymphocytes, plasma cells, and**

sometimes **epithelioid histiocytes and multinucleated giant cells**. The tumor cells have moderate amounts of cytoplasm that occasionally contain multiple small vacuoles. **Nuclei are round to slightly irregular, have fine, granular chromatin, and often have one large prominent nucleolus** (Fig. 31-54). The cytoplasm is fragile and may be stripped during smearing, resulting in peculiar streaks of basophilic material, known as a **tigroid background**, best seen on Diff-Quik preparations (Fig. 31-55). The **tigroid background is a helpful feature, but it is observed in only 39% of cases** (Caraway et al, 1995). The tumor often forms **granulomas** in metastatic sites and this feature can sometimes be recognized in smears. Cells from

P.1222

seminomas are usually positive for placental alkaline phosphatase (PLAP) and negative for CD45, CD30, HMB-45, and keratin (see Chap. 33).

Figure 31-54 Metastatic seminoma. *A.* Aspirates show a dispersed population of large cells with round nuclei and prominent nucleoli admixed with small lymphocytes. *B.* Tissue sections reveal large atypical cells and small mature lymphocytes. (*A*: high magnification.)

Both **embryonal carcinomas** (Fig. 31-56) and **endodermal sinus tumors (or yolk-sac tumors)** show cohesive groups of large cells with pleomorphic nuclei. Aspirated cells from **endodermal sinus tumors** have markedly vacuolated cytoplasm that may contain **homogeneous hyaline inclusions containing alpha fetoprotein** (Akhtar et al, 1990; see also Chap. 15). Embryonal carcinoma shows positive immunostaining for low-molecular-weight keratin and CD30.

Figure 31-55 Metastatic seminoma. The tigroid background, best seen on air-dried smears, is a helpful finding but not diagnostic of seminoma. (Diff-Quik stain, high magnification.)

Figure 31-56 Metastatic embryonal carcinoma. Aspirates show cohesive clusters of large cells with pleomorphic nuclei.

Adequate sampling of cells from metastatic germ cell tumors is helpful in detecting the dominant component, but a mixed germ cell tumor cannot be totally excluded based on cytologic evaluation alone. The cytologic observations must correlate with the clinical and biochemical findings, including the presence of serum alpha fetoprotein and human gonadotropin.

Malignant Melanoma

Lymph node aspirates of patients with malignant melanoma show a predominantly dispersed cell population, similar to malignant lymphomas. Melanoma is known as “the great mimicker” because it can have a broad variety of cytomorphologic features. Tumor cells are usually round or polygonal, but they may be spindle-shaped, pleomorphic (Fig. 31-57), small, or signet-ring-like. The round or polygonal cancer cells have abundant cytoplasm and well-defined cell

P.1223

borders. The **nuclei** are often **eccentrically located**, giving the cell a plasmacytoid appearance. Mirror-image binucleated and multinucleated cells are frequently seen; their nuclei are round to pleomorphic, have fine, granular chromatin, and have either **one prominent nucleolus or several nucleoli** (Fig. 31-58). **Intranuclear cytoplasmic inclusions** are commonly observed. **The presence of fine, granular melanin pigment (Fig. 31-59) in the cytoplasm is a helpful identifying feature, although, in a substantial proportion of aspirates of metastatic melanoma, the pigment is absent.** The pigment **stains brown** in hema-toxylineosin and Papanicolaou stains and **green** in Diff-Quik or other hematologic stains. **Melanin should be differentiated from hemosiderin, which has a coarser texture.** In cases in which melanoma is not histologically confirmed, a cytologic diagnosis of metastatic melanoma should be supported by results of ancillary studies, such as positive immunocytochemical staining for HMB-45, MART-1, or S-100 protein, or ultrastructural analysis demonstrating the presence of premelanosomes. Cangiarella et al (2000) described their experience with aspiration biopsy of metastatic melanoma in lymph nodes. Except for one false suspicious error caused by dermatopathic lymphadenopathy and two false negative results in 115 patients, the results of FNA were in concordance with histopathology and clinical follow-up data (see also Chap. 34).

Figure 31-57 Metastatic melanoma. The pleomorphic cells contain intranuclear inclusions.

Figure 31-58 Metastatic melanoma. Tumor cells characteristically have abundant cytoplasm, eccentrically placed round nuclei, intranuclear inclusions (*arrow*), and prominent nucleoli. (*A*: Diff-Quik stain; *B*: Papanicolaou stain, high magnification.)

Figure 31-59 Metastatic melanoma. Tumor cells containing pigment are diagnostic of the tumor type. (Oil immersion.)

Sarcomas

FNA is useful in documenting metastatic disease in patients with a previous diagnosis of sarcoma. Not all sarcomas metastasize to lymph nodes and those that do metastasize do so infrequently. The sarcomas that may form lymph node metastases include **rhabdomyosarcoma, clear cell sarcoma** (melanoma of soft parts), **epithelioid sarcoma, angiosarcoma, Kaposi sarcoma, synovial sarcoma, and Ewing sarcoma** (Table 31-13). Rhabdomyosarcoma occurs predominantly in children but can also be seen in adolescents and young adults. It occurs primarily in the head and neck region, genitourinary tract, upper and lower extremities, and retroperitoneum. There are **four main subtypes**, including embryonal, botryoid-type, alveolar, and pleomorphic. **Embryonal rhabdomyosarcoma** is important to keep in mind when examining the aspirates of children because it commonly metastasizes to lymph nodes and this may be the initial manifestation of the disease (see Chap. 35).

Aspirates from patients with metastatic rhabdomyosarcoma show a dispersed population of small- to intermediate-sized cells. The tumor cells are usually small, with only a thin rim of cytoplasm (Fig. 31-60), but larger cells with abundant eosinophilic cytoplasm and eccentrically located

P.1224

nuclei, and spindle-shaped cells may occur (Seidal et al, 1988). The cytologic variability is greater in rhabdomyosarcoma than in other small round cell tumors (see Table 31-6). In fact, the cells often vary, not only among patients, but also within the same tumor. **Cytoplasmic cross-striations are practically never observed** in lymph node aspirates (Kilpatrick and Geisinger, 1998) but may be observed in other media (see Chaps. 17, 26, and 35). Positive immunostaining for desmin and muscle-specific actin is helpful in confirming the diagnosis. Ultrastructural analysis demonstrates myoid differentiation, with the presence of thick and thin filaments and attempted formation of Z-bands.

TABLE 31-13 SARCOMAS THAT METASTASIZE TO LYMPH NODES

- Clear cell sarcoma (melanoma of soft parts)
- Rhabdomyosarcoma
- Ewing sarcoma
- Epithelioid sarcoma
- Kaposi sarcoma
- Angiosarcoma
- Synovial sarcoma
- Malignant fibrous histiocytoma

Figure 31-60 Metastatic rhabdomyosarcoma. *A.* Neck aspirate from a child shows small-to-intermediate cells with nuclear molding and apoptosis. *B.* Tissue section shows tumor cells infiltrating the lymph node.

Clear cell sarcoma, also known as **malignant melanoma of soft parts**, is a rare soft-tissue tumor that usually occurs in the distal extremities of young adults. Aspirates from patients with metastatic clear cell sarcoma show round to polygonal tumor cells (Fig. 31-61) with moderately abundant cytoplasm and round nuclei with prominent nucleoli (Caraway et al, 1993). Because the cytologic, immunocytochemical, and ultrastructural findings **are indistinguishable from those of metastatic melanoma**, clinical correlation is necessary to differentiate these two distinct entities.

Epithelioid sarcoma is another rare soft-tissue tumor that can metastasize to lymph nodes. It is more common in adolescents and young adults and usually arises on the finger, hand, or forearm. Aspirates show single and loose

P.1225

aggregates of cells that are polygonal to spindle-shaped (Fig. 31-62). The cells may resemble histiocytes, mimicking a granulomatous process, however, **strong positive staining for keratin** excludes a granulomatous process. The tumor cells may also appear as spindle- or tadpole-shaped cells, mimicking squamous carcinoma. In these cases, the clinical history is important.

A

B

Figure 31-61 Metastatic clear cell sarcoma (melanoma of soft parts). *A,B.* Smears show tumor cells with eccentrically placed round nuclei and occasional intranuclear inclusion. (*A*: Diff-Quik stain; *B*: Papanicolaou stain; *A,B*: high magnification).

Figure 31-62 Metastatic epithelioid sarcoma. Loosely cohesive groups of epithelial-appearing cells are present.

Figure 31-63 Metastatic angiosarcoma. *A.* Aspirate shows atypical spindle cells. *B.* Cell block preparation reveals an aggregate of spindle cells. *C.* The spindle cells show positive immunostaining for factor VIII-related antigen. (*A*: High magnification.)

Cutaneous angiosarcoma (including **Kaposi sarcoma**) arising in the head and neck region frequently metastasizes to cervical lymph nodes. Aspirates show spindle- to polygonal-shaped cells with pleomorphism (Fig. 31-63). Positive immunostaining for vimentin, Factor VIII-related antigen, and CD34 may be helpful in confirming the diagnosis.

Salivary Glands

Abdelmonem Elhosseiny

ANATOMIC AND HISTOLOGIC CONSIDERATIONS

There are two groups of salivary glands, major and minor. The major salivary glands comprise three large paired exocrine glands: parotid, submandibular, and sublingual (Fig. 32-1).

The **parotid** is the largest of the salivary glands. It is located at the angle of the mandible and encircles the ear lobe. It weighs approximately 25 g. The facial nerve divides the parotid into superficial and deep parts. Most neoplasms occur in the superficial part of the gland. The secretions of the parotid flow through Stensen's duct, opening into the oral cavity on the lateral aspect of buccal mucosa. Lymph nodes are commonly present within the parotid and in the periparotid region.

The **submandibular gland** is approximately half the size of the parotid. It is located in the submandibular triangle between the inferior border of the mandible and the digastric muscle. Warthin's duct carries the secretions of the submandibular gland to the floor of the mouth. There are no lymph nodes within the submandibular gland, though a few lymph nodes are adjacent to it in the submandibular triangle.

The **sublingual gland** is the smallest of the major salivary glands and weighs approximately 3 g. It is located in the floor of the mouth in the lingual sulcus. Secretions of the sublingual gland are carried in multiple small ducts to the oral cavity.

Several hundreds of tiny **minor salivary glands** are scattered throughout the mucosa of the oral and nasal cavities, larynx, and bronchial tree. They are most abundant in the posterior hard palate. The secretions of minor salivary glands are carried to the oral cavity by short excretory ducts (Ellis and Auclair, 1996).

Ectopic Salivary Gland

Ectopic salivary gland tissue is most commonly encountered as an **incidental finding in periparotid and intraparotid lymph nodes** (Fig. 32-2A) (Silvers and Som, 1998). These lymph nodes may play a role in the pathogenesis of Warthin's tumor and are a potential site of inflammatory lesions or metastases from tumors in adjacent and distant locations (Ellis and Auclair, 1996). Less commonly, ectopic salivary

P.1230

tissue can be seen in soft tissues along the anterior border of the sternocleidomastoid muscle and in cervical lymph nodes (Lassaletta-Atienza et al, 1998). Rarely, tumors of salivary gland origin, both benign and malignant, may develop in these sites.

Figure 32-1 Diagrammatic representation of the anatomy of the three major salivary glands.

Figure 32-2 *A.* Paraparotid lymph node with inclusions of salivary gland ducts. Immunoperoxidase reaction for epithelial cytokeratins. *B.* Parotid gland with an acinar island showing sebaceous differentiation. *C.* Parotid gland of a newborn. Note the absence of fat. *D.* Parotid gland of an adult. With increasing age, there is a decrease in the density of parenchymal glandular tissue and replacement by fat. Loss of parenchyma with replacement by fat may also occur in younger adults following irradiation.

Histology

The fundamental structure of both major and minor salivary glands comprises **acinar** and **duct**

units. The **acini of serous, mucinous, or mixed seromucinous types** are arranged in groups or lobules surrounded by a basement membrane. The cells in serous acini are approximately triangular with their narrowest part facing the luminal surface; their cytoplasm is basophilic and granular. The nuclei are round, uniform, and basally located. The mucinous cells have similar shape but their cytoplasm is clear or finely granular; the nuclei are also round and basally located. Sebaceous differentiation is sometimes noted (Fig. 32-2B) and well-formed **sebaceous glands have been reported** in 10% to 42% of normal salivary glands (Martinez-Madrigal et al, 1997). Saliva that is formed in the acini flows through a series of ducts, described below, and into the oropharyngeal cavity. The **parotid is almost exclusively serous; the sublingual gland is mostly mucinous; and the submandibular gland is seromucinous.** The composition of the saliva is determined by the histology of the acini. In young persons, the acinar cells are closely apposed (Fig. 32-2C) but with advancing age, the amount of interstitial adipose tissue increases while parenchymal tissue decreases (Fig. 32-2D) (Ellis and Auclair, 1996).

P.1231

The duct system of the major salivary glands is divided into three distinct parts: the intercalated, the striated, and the excretory (interlobular) ducts (Fig. 32-3). The intercalated duct, which lies within and receives the secretions of an acinus, is very short and lined by simple cuboidal epithelium. The striated ducts are lined by columnar epithelium with basal striations and are much larger than the intercalated duct. The excretory or interlobular ducts are the terminal part of the duct system and are lined by stratified columnar epithelium that changes to squamous epithelium as the ducts approach the oral cavity. **Myoepithelial cells** are present at the periphery of the acini and along the outside of the intercalated ducts.

INDICATIONS FOR FINE-NEEDLE ASPIRATION

Fine-needle aspiration (FNA) cytology has now been accepted by head-and-neck surgeons as an excellent, though challenging, **primary method** of evaluating space-occupying lesions of the salivary glands (Zajicek, 1974; Batsakis et al, 1992; Boccato et al, 1998). Used correctly, it

can provide a definitive diagnosis when clinical findings and radiographic studies are not adequate to distinguish nonneoplastic from neoplastic lesions, or benign from malignant tumors. It has advantages over an operative incisional biopsy, which has the potential risk of fistula formation and, in the case of malignant neoplasms, the theoretical possibility of seeding tumor cells.

FNA of salivary glands generally address the following questions:

- Is the mass of salivary gland origin?
- If the mass is of salivary gland origin, is it neoplastic or non-neoplastic?
- If the mass is neoplastic, is it benign or malignant?
- If the mass is malignant, is it primary or metastatic?

If primary, what is the tumor type?

If metastatic, what is the site of origin?

The diagnosis rendered by FNA often influences management of the patient (Zajicek, 1974; Kocjan et al, 1990; Orell, 1995) and allows for appropriate treatment planning. For example, if a tumor is benign, surgical intervention may be delayed or modified, whereas a malignant neoplasm may call for prompt surgical treatment or irradiation. The diagnosis of lymphoma calls for still other investigative and treatment options.

Lesions of the skin and subcutaneous tissues overlying the salivary gland, for example, epidermal inclusion cysts, lipomas, tumors of sweat glands, basal cell carcinomas, or schwannoma, may be mistaken for a salivary gland tumor (see below). It should also be noted that an enlargement of a salivary gland may be caused by a nonneoplastic cyst, reactive intraparotid lymph node, stones, or sialadenitis.

As mentioned earlier, lymph nodes within the parotid or peri-parotid region may be the site of metastatic tumor, lymphoma, and inflammatory or reactive processes.

Complications of FNA of Salivary Gland

Significant complications of fine-needle aspirates of salivary gland are rare. Kern (1988) described postaspiration necrosis in a case of Warthin's tumor and Layfield et al (1992) described similar occurrences in cases of pleomorphic adenoma. Stephen et al (1999) reported xanthogranulomatous sialadenitis following needle aspiration of Warthin's tumor. Li et al (2000) and Mukunyadzi et al (2000) reviewed the histology of a large number of salivary gland lesions previously sampled by FNA. They observed that areas of **infarction, necrosis, hemorrhage, inflammation, and granulation tissue** were quite common but did not interfere with the final histologic diagnosis. A potential source of error is the presence of **exuberant squamous metaplasia** of ducts, apparently induced by aspiration, which in some cases was marked enough to mimic a mucoepidermoid or squamous cell carcinoma. Obviously, knowledge of a prior aspiration procedure may be valuable in the interpretation of tissue samples. There has been no report known to us of tumor implantation following salivary gland aspiration.

CYTOLOGY OF NORMAL SALIVARY GLANDS

It is important to be familiar with cytologic features of normal salivary glands, which may be observed in needle aspirates of a prominent but normal salivary gland or failure to sample the target lesion.

The typical aspirate is composed of acinar cells, duct cells, and adipose tissue. **Acinar cells form cohesive, spherical groups composed of polyhedral cells with vacuolated or granular cytoplasm and small, uniform nuclei** (Fig. 32-4A-C). An entire lobule is often present with intervening adipose tissue. The **duct cells form either flat honeycomb sheets of small, uniform cuboidal cells with centrally located round nuclei, or tight tubular structures composed of similar cells** (Fig. 32-4D).

NONNEOPLASTIC LESIONS

Cystic lesions

Cysts may involve acinar tissue of the salivary glands or their ducts; they are more frequently encountered in minor salivary glands.

Mucocele

A mucocele is a mucus-filled cyst, in or around a minor salivary gland, caused by rupture of the gland with extravasation of mucus into adjacent tissues. **The cyst has a fibrous wall lined by granulation tissue, and contains macrophages as well as mucus.** Mucoceles present clinically as a raised, painless, soft or fluctuant nodule. They may arise anywhere in the oral cavity, but the lower lip is the most common site.

Retention Cyst

Retention cysts are closely related to mucoceles, but much less common. They are encountered more frequently in major salivary glands, particularly the parotid, and result from

duct obstruction by microliths or inspissated secretions (Fig. 32-5). Patients are usually older than those affected by mucocele. Retention cysts are true cysts with an epithelial lining that may be columnar, squamous, or mucus-secreting. The most important consideration in the differential diagnosis is a low-grade mucoepidermoid carcinoma. Jayaram et al (1998) reported an **erroneous diagnosis of squamous carcinoma** in a patient with atypical squamous metaplasia of a cyst formed by dilated salivary duct.

Figure 32-5 Impacted stone. Floor of mouth of a patient with stone impacted at the orifice of Warthin's duct of the submandibular gland, just to the left of the frenulum of the tongue (arrow).

P.1233

Cytology

An aspirate of a mucocele or retention cyst yields clear or mucoid fluid. The cell content is scanty, but there are usually a few macrophages, with or without other inflammatory cells, and a few epithelial cells. Rarely, metaplastic oncocytic cells may be present but they are few in number and not associated with lymphocytes, as in Whartin's tumor (see below). Normal salivary gland tissue may be seen if the aspirating needle has passed through normal gland. If the cyst collapses completely following aspiration, the aspiration may be considered as a curative procedure. **It is very important to verify that there is no residual mass after aspiration; its presence indicates that a solid tumor is hiding behind the cyst and repeat aspiration or biopsy are strongly recommended.** If a cyst recurs multiple times, surgical excision is the treatment of choice (Zarka, 1996).

Benign Lymphoepithelial Cysts

These cysts are typically seen in adults and most are unilateral. They present within, or around, the parotid and are usually well circumscribed. Previously rare, such cysts have been observed with increasing frequency in **patients with acquired immunodeficiency syndrome (AIDS)**. **The HIV-associated lymphoepithelial cysts** are more **frequently bilateral** and often

accompanied by diffuse cervical lymphadenopathy. Stigmata of AIDS may be evident, including Kaposi's sarcoma, oropharyngeal herpes, or monilial infections. The cysts are **lined by squamous epithelium and surrounded by dense lymphoid tissue** with reactive lymphoid follicles (Wiedner et al, 1986). The **histologic structure and cytology of the HIV-associated cysts are identical to the benign lymphoepithelial cysts** (Fig. 32-6) (Finfer et al, 1990).

Cytology

Aspirates contain an abundant, **heterogeneous population of reactive lymphocytes and macrophages in clear cyst fluid**. In addition, there may be a few small clusters of squamous or sometimes columnar or cuboidal epithelial cells (Elliot and Oertel, 1990). Lopez-Rios et al (1999) reported the presence of **crystalloids** identified as **crystallized amylase** in cyst fluid from two such patients. For further discussion of crystalloids in salivary gland lesions, see below. Vicandi et al (1999) reported the presence of numerous **multinucleated giant cells** in two HIV-infected patients. The presence of viral protein could be demonstrated in these cells by immunocytochemistry with p24.

Figure 32-6 HIV-associated lymphoepithelial cyst of parotid showing a dense lymphoid infiltrate with centrally cystic space filled with pink secretory material.

Nonneoplastic Solid Lesions

Acute Sialoadenitis

Acute inflammatory lesions of salivary glands are commonly caused by **stasis of secretions with microliths** (Fig. 32-7A) and **bacterial infection**, or may be caused by **cytomegalovirus (CMV) or mumps** (Wax and Layfield, 1994). Patients with acute sialoadenitis present with tenderness and diffuse enlargement of the affected gland.

Cytology

Aspiration is rarely necessary to make the diagnosis but if performed, it yields **numerous polymorphonuclear leukocytes**, frequently associated with cellular debris, macrophages,

and proteinaceous background. Fragments of regenerative acinar or ductal tissue may be present.

Chronic Sialoadenitis

Chronic inflammation of salivary gland is either the result of duct obstruction caused by stones (sialolithiasis), or by physical, microbial, or immunological injuries. It is a common complication of radiotherapy of head and neck cancers and may result in **xerostomia** (dry mouth).

The end stage of chronic sialoadenitis is **atrophy of the acini and stromal fibrosis**, usually resulting in a firm gland that clinically may simulate a tumor (Fig. 32-7B,C) (Chai et al, 1997).

Cytology

Aspirates of salivary gland, with **chronic sialoadenitis**, are generally scanty and contain a few lymphocytes, plasma cells, some neutrophils, cellular debris, and macrophages in a background of mucus. Rarely, fragments of glands or of fibrous tissue will be present in the aspirate. In cases of **sialolithiasis**, cystic dilatation of ducts may occur. Such ducts may show marked proliferation of ductal epithelium resulting in formation of mucoid material.

Squamous metaplasia of the epithelium may also occur. An **aspiration** smear in such cases may show calcified debris of stones and atypical squamous cells in the background of mucus, sometimes mimicking mucoepidermoid carcinoma (Stanley et al, 1996). A case of chronic sialadenitis with numerous **psammoma bodies** mimicking cancer was described by Frierson and Fechner (1991).

Granulomatous Sialoadenitis

This form of chronic sialoadenitis may have several possible causes, including tuberculosis and sarcoidosis (Aggarwal et al, 1989). Duct obstruction, caused by a stone or tumor, is one potential cause of granulomatous inflammation. Xerostomia is uncommon in unilateral disease and in the absence

P.1234

of lithiasis, these patients may be asymptomatic. In **sarcoidosis**, the granulomas are usually **bilateral**, frequently involve surrounding lymph nodes, and may involve other organs, including lung (see Chap. 19). Unfortunately, many cases of granulomatous sialoadenitis remain without identifiable cause.

Figure 32-7 Stages of chronic sialadenitis. *A.* Histologic sections of submandibular gland showing a calculus within a small collecting duct with periductal inflammation. *B.* Early stage of inflammation. There is a dense lymphocytic infiltrate with mild fibrosis and some loss of acini. *C.* Late stage. Marked fibrosis, lymphocytic infiltrate and complete loss of acini while the ducts are preserved. The affected glands are hard on palpation and yield very scanty material on aspiration.

Cytology

The granulomas are focal and may be difficult to sample. If representative material is obtained, however, the smears may sometimes contain whole granulomas (Fig. 32-8A). More often, however, the smears show aggregates of **carrot-shaped, spindle epithelioid cells and sometimes well-formed giant cells in a background of lymphocytes and plasma cells** (Fig. 32-8B,C). Special stains and bacterial culture may be needed to search for microorganisms if tuberculosis or other infectious agents are suspected.

Benign Lymphoepithelial Lesions

Myoepithelial Sialoadenitis

These benign lymphoepithelial **autoimmune** lesions are characterized by a progressive, destructive **lymphocytic infiltrate** of salivary (and lacrimal) glands resulting in loss of acini (Fig. 32-9A). There is proliferation of myoepithelial cells with preservation of the ducts, leading to the formation of **epithelial-myoepithelial islands**; hence, the name of **myoepithelial sialoadenitis** that is now attached to this disorder.

The lesion is closely associated with **Sjögren's syndrome**, in which the affected individuals experience dryness of the mouth and eyes (xerostomia and xerophthalmia), caused by the autoimmune destruction of salivary and lacrimal glands. It may occur in association with other auto-immune disorders such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or polymyositis.

Cytology.

Aspiration smears show small tight clusters of **epithelial-myoepithelial cells within a heterogeneous population of lymphocytes** and occasional tingible body macrophages (Fig. 32-9B). Rare microcalcifications may be present. The epithelial-myoepithelial cells may be difficult to find or to identify in smears. In such cases, the diagnosis may be suspected based on the history and nature of the inflammatory reaction, but difficult or impossible to prove by cytology.

Necrotizing Sialometaplasia

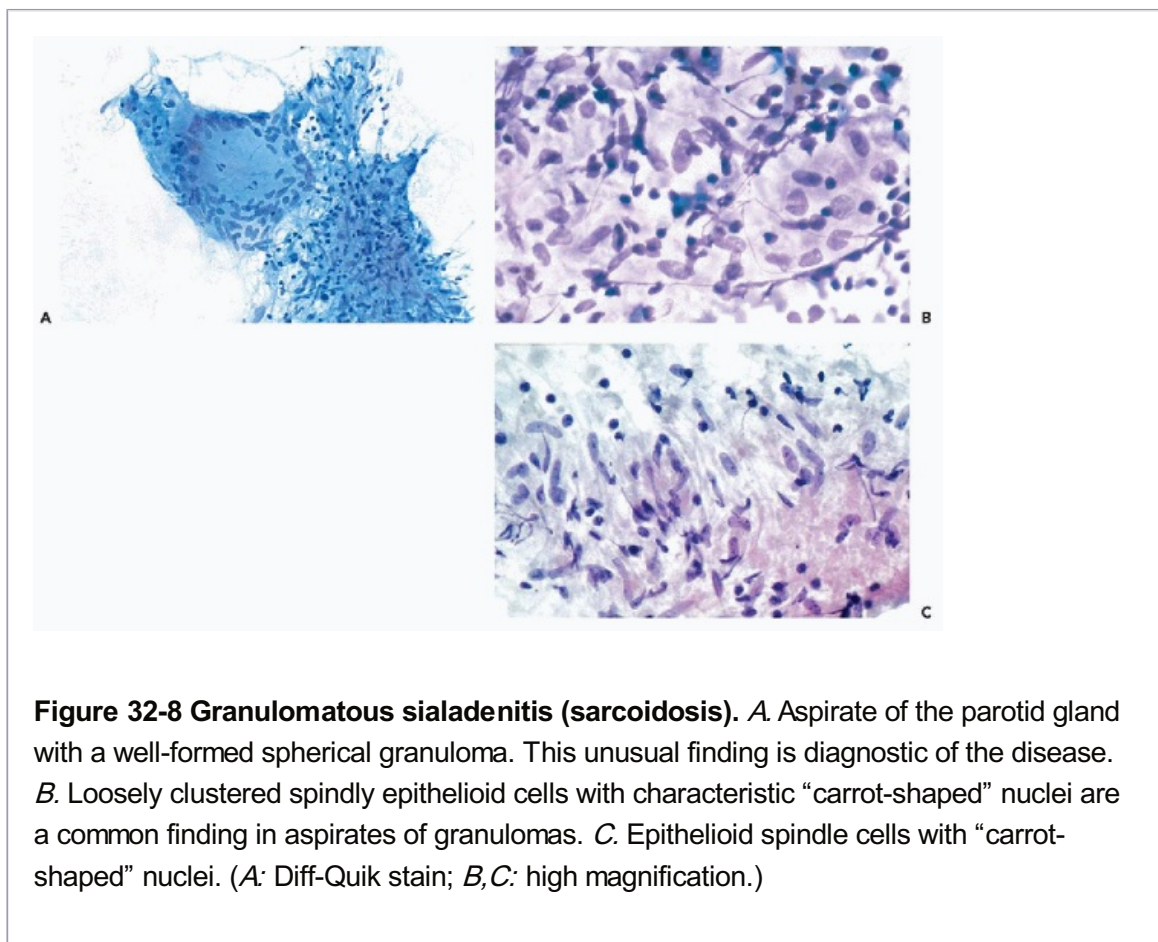

A necrotizing, often ulcerative, sialoadenitis most commonly affects minor salivary glands of the palate. It is a self-limited disease of unknown etiology. Histologically, lobular necrosis and sialoadenitis are accompanied by squamous metaplasia of the ducts or acini (Brannon et al, 1991).

Cytology.

An aspirate yields **islands of metaplastic squamous epithelium within a background of mucus with few inflammatory cells**. Mucin-secreting epithelial cells

P.1235

may be present and squamous cells may show some inflammatory atypia. **Careful history and the typical clinical presentation are important in avoiding an erroneous diagnosis of squamous or mucoepidermoid carcinoma.**

BENIGN NEOPLASMS

Most tumors of the salivary glands are benign. The principal types of these tumors are listed in Table 32-1.

Pleomorphic Adenoma (Benign Mixed Tumor)

Clinical Data

Pleomorphic adenomas (PA) are the most common salivary gland tumors; they constitute 60% to 70% of all parotid tumors, approximately 50% of tumors in the submandibular glands, and 40% to 70% of all tumors of the minor salivary glands.

Ninety percent of the parotid tumors occur in the superficial lobe. The two most common sites for PA arising in minor salivary glands are the lip and palate. Rarely, PA may

P.1236

arise from ectopic salivary tissue at **unusual sites**, as for example in cervical lymph nodes and soft tissue of the neck, the breast, the lacrimal glands, or skin of upper and lower extremities. The skin lesions are of sweat gland origin and are usually referred to as **chondroid syringoma** (Surana et al, 1993; Lassaletta-Atienza et al, 1998).

TABLE 32-1 PRINCIPAL BENIGN TUMORS OF SALIVARY GLANDS

- Pleomorphic adenoma
- Warthin's tumor
- Oncocytoma
- Monomorphic adenoma
- Basal cell adenoma

PA typically presents as a discrete, painless, firm, mobile mass in a major salivary gland (Fig. 32-10A), or as a painless submucosal nodule in a minor salivary gland. A tumor of the parotid or the submandibular gland may be mistaken clinically for an enlarged lymph node and vice-versa.

A preoperative diagnosis of PA is of significant clinical value as it should alert the surgeon that the tumor **must be carefully removed with its capsule intact**. Incomplete removal may result in a **recurrence** of the tumor in the form of multiple, disfiguring subcutaneous nodules, sometimes many years after surgery.

On the rarest occasions, PA may form **metastases to neck lymph nodes, lung, and other organs**. Such tumors cannot be distinguished morphologically from the nonmetastasizing variety (Gerughty et al, 1969; Spiro et al, 1977; Chen, 1987).

Histology

PA is a tumor of diverse histologic appearance. It comprises a mixture of epithelial, myoepithelial, and stromal mesenchymal components (Fig. 32-10B). The presence and the prominence of each component may vary in different parts of the same tumor, and from tumor to tumor. Some pleomorphic adenomas are very cellular, composed of sheets of epithelial cells with only scanty stroma; in others stroma predominates. **The epithelial cells may form solid sheets of cells, tubules, ducts, acini, or trabecula**. Foci of **squamous metaplasia**, with or without keratin formation, **oncocytic metaplasia**, **mucus gland formation**, or sometimes **sebaceous differentiation** may occur within the epithelial structures. **The myoepithelial cells produce the mesenchymal stromal component that may be myxoid, chondroid, or hyalinized. Blending of the epithelial structures with the stroma is one of the most characteristic features** of this tumor.

The myoepithelial cells in the chondromyxoid stroma are typically stellate or round, but in cellular areas, they may be spindly, plasmacytoid, or polygonal in appearance (Ellis and Auclair, 1996). The nuclei of spindly myoepithelial cells are generally hyperchromatic and tapered. Plump, spindle-shaped myoepithelial cells with eosinophilic cytoplasm can resemble cells of leiomyoma. The myoepithelial cells may also form **small clusters** mimicking epithelial cells.

Tyrosine crystals were initially described by Bottles et al (1984) in a case of pleomorphic adenoma. In other PAs, **oxalate** and yellow **hippurate** crystals have been identified (see below).

Cytology

The cytologic features of PA are usually quite characteristic and the correct diagnosis can be readily established on an adequate specimen in most cases (Koss et al, 1992; Dardick et al, 1999). **Although the aspirate is usually rich in cells, it is the presence of the chondromyxoid stroma, often containing capillary vessels, that is of critical diagnostic value** (Fig. 32-10C). The stromal cells are slender, spindly, or stellate mesenchymal cells that may be found singly or in clusters (Fig. 32-10D). They commonly merge imperceptibly with epithelial cells, but epithelial cells may be entirely separate (Fig. 32-10E). The chondromyxoid stroma forms irregularly shaped structures that stain **gray-green in Papanicolaou stain** (Fig. 32-10F), or **intensely red or purple with hematologic stains** (Fig. 32-10G). Cellularity is variable, as is the ratio of epithelial cells to stroma, with some tumor fragments composed mainly of stroma and others formed mainly by epithelial cells (Frale and Frable, 1991).

The epithelial cells usually form loosely cohesive clusters that are sometimes of papillary configuration, but may also be arranged in flat sheets or sometimes tubules,

and are typically intermixed with the chondromyxoid stroma (Fig. 32-10F). When in sheets, the epithelial cells are of equal size with scanty, pale cytoplasm and round or slightly oval nuclei with fine, evenly textured chromatin (Fig. 32-10E). Murty and Sodhani (1993) reported the presence of **intranuclear cytoplasmic inclusions**. Occasional larger epithelial cells, with well-defined eosinophilic cytoplasm and eccentric small nuclei, may be observed, but nuclear chromatin is finely granular and evenly distributed, often with tiny nucleoli (Klijanienko and Vielh, 1996). Also, **in rare instances, epithelial cells with basaloid features are arranged in ball-like structures**, as commonly observed in adenoid cystic carcinoma (see below) (Elshiekh and Bernacki, 1996).

P.1237

Figure 32-10 Pleomorphic adenoma (mixed tumor) of parotid gland. *A.* Gross appearance of a well-circumscribed, lobulated, firm white tumor mass. *B.* Histologic section shows the epithelial component and myxoid or chondromyxoid stroma; the latter is often a key diagnostic component in the needle aspirates. The epithelium forms ductal structures, may be undifferentiated or basaloid with hyalinized stroma, mimicking adenoid cystic carcinoma, or it may undergo squamous differentiation with keratinization. It can vary from area to area

within the same tumor. *C.* Thin-needle aspirate of pleomorphic adenoma at high magnification showing characteristic faintly bluish chondromyxoid material with capillaries. *D.* Myoepithelial and myxoid stromal cells. *E.* A cluster of epithelial cells. *F.* Diff-Quik stain showing transition between islands of epithelial cells and chondromyxoid stroma. *G.* Magenta-staining chondromyxoid stroma in Diff-Quik. *H.* Loosely distributed, bland-appearing "plasmacytoid" myoepithelial cells with round nuclei (hyaline cells). (*C,E-H*: High magnification.)

P.1238

The **myoepithelial cells** may form clusters of loosely cohesive cells. Individual cells may have a spindle or plasmacytoid appearance with indistinct cytoplasmic borders (Fig. 32-10H). Such cells cannot be readily differentiated from epithelial cells.

Various types of metaplasia that have been observed in PA, as described above, are seldom evident in the needle aspirate. **When either squamous, oncocytic, sebaceous, or mucinous metaplasia is prominent, the possibility of a low-grade mucoepidermoid carcinoma must be considered** (Stanley and Löwhagen, 1990). Rarely, aspirates of benign PA have been reported to contain **calcifications resembling psammoma bodies** (Qizilbash et al, 1985).

When present, **crystalloids are useful in confirming the diagnosis of PA**. Several different varieties of crystals have been identified. **Tyrosine crystalloids** usually form yellow or pink leaf-shaped structures (Fig. 32-11A,B) but may also form needle-shaped and tubular crystals (Lopez-Rios et al, 1999). Other crystalloids are the polygonal, yellow-staining **hippurate** crystals (Fig. 32-11C), needle-shaped **oxalate** crystals, radially arranged needle-shaped **collagenous** crystals and multifaceted **amylase** crystals with pointed ends (Campbell et al, 1985; Sugihara et al, 1998). Only tyrosine crystals have been reported in low-grade adenocarcinomas of salivary glands (Raubenheimer et al, 1990; Lopez-Rios, 1999). So far as is known today, all other crystalloids have been observed only in benign PA.

Figure 32-11 Crystalloids in benign pleomorphic adenomas. *A.* Leaf-shaped yellow tyrosine crystal in FNA of a parotid tumor. *B.* Similar crystals in tissue section. *C.* Polygonal

hippurate crystals.

Diagnostic problems in PA can arise when there is selective sampling with little or no chondromyxoid ground substance and the lesion may be interpreted as a carcinoma. Also, the presence of many single atypical epithelial cells may raise the possibility of **carcinoma ex pleomorphic adenoma**. Landolt et al (1990) reported the cytologic diagnosis of a **metastatic mixed tumor (PA) to the lung**. The principal features of pleomorphic adenoma and its differential diagnosis are summarized in Table 32-2.

Warthin's Tumor (Adenolymphoma)

Warthin's tumor, also known as papillary cystadenoma lymphomatosum, or adenolymphoma, is the second most frequent benign tumor arising in the parotid.

It is a slowly growing, soft, usually cystic, painless tumor, often described as “doughy” (Fig. 32-12A). **It arises almost exclusively in the lower pole of the parotid gland, and affects mainly men in the sixth or seventh decades of life.** Occasionally, the tumor may arise in peri-parotid lymph nodes. The cysts, of variable sizes, contain turbid,

P.1239

yellow, sticky fluid, accounting for the spongy consistency of the tumor. The tumor is **multifocal** or **bilateral** in approximately 10% of cases (Ellis and Auclair, 1996). There appears to be a close association between Warthin's tumor and cigarette smoking (Brandwein and Huvos, 1991). No relationship has been established with Epstein-Barr virus (EBV) (van Heerden et al, 1999).

TABLE 32-2 PRINCIPAL CYTOLOGICAL FEATURES OF PLEOMORPHIC ADENOMA
Cellular smears composed of epithelial cells blending with fibromyxoid background
The presence of fibromyxoid stroma
The presence of crystalloids
<i>Differential Diagnosis</i>
Adenoid cystic carcinoma, if the epithelial cells form ball-like structures
Low-grade mucoepidermoid carcinoma, if there is an extensive squamous metaplasia

Figure 32-12 Warthin's tumor. *A*. The gross appearance of a “doughy” multicystic, tan tumor, strikingly different in gross appearance and texture from the pleomorphic adenoma (mixed tumor), which is a firm, discrete, lobulated white mass (see Fig. 32-10A). The “feel” upon insertion of the needle may provide a diagnostic clue. *B*. Histologic sections show a multicystic tumor with oncocytic cells surfacing papillary intracystic projections of lymphoid tissue with prominent follicles, hence the alternative name “papillary cystadenoma lymphomatosum.” *C,D*. Thin-needle aspirate of Warthin's tumor showing prominent oncocytic epithelial cells with abundant deeply eosinophilic cytoplasm. The oncocytic cells may form flat sheets (*C*), overlapping groups, or occur as single cells. The granular features of the cytoplasm are better visualized with Diff-Quik stain (*D*). The background of the smears is formed by precipitated cyst fluid with lymphocytes.

Histology

Warthin's tumor has a distinctive histologic appearance. **It is composed of oncocytic epithelium, arranged in papillary fronds, lining clefts or cystic spaces. The stroma of the tumor is densely infiltrated with lymphoid tissue** (Fig. 32-12B). The epithelium is arranged in two layers: inner columnar and outer cuboidal cell layers. The lymphoid stroma frequently includes reactive **lymphoid follicles**. In unusual cases **sarcoid-like granulomas** have been described (Rysska et al, 1999). Rarely, transformation into a lymphoma has been reported (Park et al, 2000). Squamous or mucinous metaplasia of the lining epithelium may

P.1240

be present (Klijanienko and Vielh, 1997). The cyst contents are a mucoid, brownish material with degenerated epithelium, cellular debris, cholesterol clefts, and variable numbers of macrophages (Mandel and Tomkoria, 2000).

Cytology

The aspirate usually yields up to several milliliters of turbid brownish fluid; some compare it to motor oil. **Smears from Warthin's tumor typically contain three components: oncocytic cells, reactive lymphocytes, and cellular debris in a mucoid background.** The most characteristic component is the many **oncocytic cells, which are easily recognized as large**

epithelial cells with abundant, densely eosinophilic, granular cytoplasm that is rich in mitochondria (see Fig. 32-11C,D). They are arranged in flat, cohesive sheets, occasionally forming tight papillary fronds. A mixed population of reactive lymphocytes with tingible body macrophages usually forms the background of the smear. The mucoid cyst fluid usually contains cellular debris, macrophages and isolated epithelial cells with pyknotic nuclei. Not infrequently, neutrophils also are seen. Nontyrosine crystalloids have been described in the cyst contents (Nasuti et al, 2000).

The aspirates may also contain clusters of **squamous cells** or mucin-producing **goblet cells** derived from foci of squamous or mucinous metaplasia. In the presence of these components, the differential diagnosis includes branchial cleft cyst and low-grade mucoepidermoid carcinoma. **Infarction** of Warthin's tumor has been reported as a rare complication of aspiration (DiPalma et al, 1999). The primary features of Warthin's tumor and its differential diagnosis are summarized in Table 32-3.

Oncocytoma

These are **rare, benign, solid tumors of salivary glands**, accounting for less than 1% of all salivary gland tumors. They may **occur in the parotid, submandibular, or minor salivary glands**. The average age of these patients is about 70 years, and women are somewhat more often affected than men. The patients usually present with an asymptomatic swelling of a salivary gland.

TABLE 32-3 PRINCIPAL CYTOLOGICAL FEATURES OF WARTHIN'S TUMOR

Abundant oncocytes arranged in sheets, clusters, or occurring singly

Background of lymphocytes, mucoid material and cell debris

Occasionally, squamous and goblet cells are observed.

Differential Diagnosis

Oncocytoma

Rarely squamous cell carcinoma or low-grade mucoepidermoid carcinoma in the presence of extensive squamous metaplasia

The tumor is usually well demarcated or encapsulated, and composed of **uniform oncocytic cells arranged in solid, tubular, or trabecular patterns**. The **individual cells are polygonal, with characteristically abundant granular eosinophilic cytoplasm** and round nuclei with eccentric nucleoli (Fig. 32-13A,D). **Clear cell transformation** may occur in some tumors due to glycogen deposit in the cytoplasm. However, the cell pattern remains unchanged (Brandwein and Huvos, 1991). There is no evidence of mitotic activity. **Psammoma bodies** have been observed in this tumor (Palmer et al, 1990).

Cytology

The aspiration smears show **sheets of tightly packed polygonal oncocytic cells with abundant, deeply eosinophilic granular cytoplasm, and uniform round central nuclei with prominent slightly eccentric nucleoli**. The **absence of lymphocytes** and cellular debris are the most important features differentiating this tumor from Warthin's tumor (Fig. 32-13B,C). It is not known whether the very rare **oncocytoid adenocarcinoma** is derived from benign oncocytoma. Such a case was described by Austin et al (1987).

Oncocytosis

Oncocytosis refers to a nodular or diffuse hyperplasia of oncocytes within the salivary gland, without encapsulation or formation of a discrete mass (Palmer et al, 1990). Oncocytosis may be **very extensive** and replace a significant portion of the affected gland. Dardick et al (1999) pointed out that focal oncocytic metaplasia may be observed in many conditions and tumors of salivary glands. This change may be artificially induced by electrocautery (Shick and Brannon, 1998). **Differentiation from oncocytoma by cytology alone is impossible** (Eneroth and Zajicek, 1965). In a personally observed case, the cytologic presentation of an extensive oncocytosis was identical to an oncocytoma.

Basal Cell Adenoma

This relatively uncommon benign neoplasm has been considered a prototype of a group of salivary gland tumors collectively known as **monomorphic adenomas**. Because of significant confusion concerning the classification of these tumors, the term is no longer recommended by WHO (Simson, 1994) but it is still used. As defined by Seifert and Sobin (1992), basal cell adenoma is a "tumor of basaloid cells with distinct basement membrane-like material that lacks chondromyxoid stroma."

Seventy percent of these tumors occur in the parotid, with the remainder occurring in the submandibular gland, and the minor salivary glands, especially in the upper lip.

P.1241

The least common sites are the buccal mucosa and the palate. The tumor is observed more often in women, and most of the patients are elderly. Clinically, it presents as a painless, solid, mobile nodule varying in size from 2 to 3 cm (Batsakis et al, 1991).

Figure 32-13 Oncocytoma. *A.* Histologic appearance is that of a homogeneous population of oncocytic cells with occasional fat cells. Note that the ducts are absent. *B.* The cytology of a needle aspirate is characterized by oncocytic cells as in Warthin's tumor but without lymphocytes. Broken cells, stripped nuclei and granular cytoplasmic debris form the background. *C,D.* Smear and cell block section of another case showing the same features.

Histology

This encapsulated tumor is composed of small basaloid cells with a peripheral palisade arrangement, mimicking basal cell carcinoma of the skin (Fig. 32-14A).

Histologic patterns may be trabecular (60%), tubular (30%), solid, or membranous. In the trabecular form, the tumor cells are arranged in 3 to 4 cell-thick cords, separated by basement membrane. In the tubular type, the cells form tubules with distinct lumens resembling salivary ducts (Fig. 34-14F). The tubular or canalicular type of monomorphic adenoma more frequently involves the upper lip and is regarded by some as a special entity, but does not have any special therapeutic or prognostic significance (Zarbo et al, 2000). The membranous pattern is characterized by marked production of basement membrane-like material (Batsakis et al, 1983). Any of the monomorphic adenomas may exhibit focal oncocytic or sebaceous differentiation.

Cytology

Aspiration smears yield numerous **uniform small cells** with sparse, pale, basophilic cytoplasm, and bland, round to oval nuclei with granular chromatin and small chromocenters. They often are present in clusters or sometimes branching cords. A variable amount of **amorphous, eosinophilic, stromal basement membrane-like material is present**, usually adjacent to the cell clusters (Fig. 32-14B). Occasionally, the amorphous material is spherical and surrounded by small epithelial cells, **mimicking adenoid cystic carcinoma** (Fig. 32-14C,D). In some cases of **tubular adenoma** (Fig. 34-14E), the aspiration smear contains cohesive clusters of small epithelial cells, similar to those observed in the trabecular type (Fig. 34-14B-D). In this particular case, the hyaline material was not evident in the smear. Kljianienko et al (1999) reported seeing **squamous cells and debris** in two of their cases of basal cell adenoma, rendering the differential diagnosis very difficult. Gupta (1996) reported a case of **dermal anlage tumor** of the parotid, a subtype of monomorphic adenoma. The smears were characterized by the presence of basement membrane-like material besides the clusters of small, uniform epithelial cells. Drut and Quijano (1999) described an unusual case of atypical **plasmacytoid variant** of monomorphic adenoma.

P.1242

Figure 32-14 Basal cell adenoma. *A.* Histologic sections show a discrete tumor mass composed of uniform basaloid cells in islands with peripheral palisade arrangement. *B-D.* High magnification of a thin-needle aspirate of basal cell adenoma showing loosely cohesive clusters of small monotonous appearing basaloid cells adjacent and intermingled with eosinophilic homogeneous material. If the basement membrane-like material is spherical and surrounded by basal cells, it resembles adenoid cystic carcinoma (*C,D*) (compare with Fig. 32-18). *E,F.* Trabecular adenoma. *E.* A cluster of small tumor cells without distinguishing features. *F.* The tubular configuration of the tumor with homogeneous material filling the lumens.

The cellular pleomorphic adenoma and adenoid cystic carcinoma must be considered in the differential diagnosis of basal cell adenoma. The absence of chondromyxoid background is helpful in ruling out pleomorphic adenoma (Stanley et al, 1988, 1996). **The differential diagnosis between a basal cell adenoma and adenoid cystic carcinoma,** which is described below, is occasionally **very difficult**, particularly if the hyaline deposits are spherical and surrounded by epithelial cells, as shown in Figure 34-14C. In general, the basement membrane globules of monomorphic adenomas are usually smaller than those of adenoid cystic carcinoma but the difference is often trivial. However, in adenomas the uniform cells with inconspicuous nucleoli usually **form flat sheets rather than multilayered clusters**, characteristic of adenoid cystic carcinoma (Hood et al, 1983; Stanley et al, 1988). Still, in some cases, only the

P.1243

histologic examination of the excised tumor yields the correct diagnosis.

The rare basal cell carcinoma, originating in a basal cell adenoma, is also a consideration in the **differential diagnosis** that depends on the presence or absence of an infiltrative tumor border, a feature that cannot be appreciated in cytologic aspirates (Nagao et al, 1997). There are cases of basal cell adenocarcinoma reported to have had residual evidence of monomorphic adenoma (Luna et al, 1989).

Cutaneous cylindromas, tumors of sweat glands, may overlie salivary glands and be mistaken for the solid variant of basal cell adenoma in an aspirate, hence the importance of careful physical examination at the time of the aspiration.

The principal features of basal cell adenoma and its differential diagnosis are summarized in Table 32-4.

Rare Benign Tumors

Myoepithelioma

This tumor is extremely rare in the salivary glands; it is somewhat more common in the breast, and the reader is referred to Chapter 29 for description. Dodd et al (1994) described the cytologic findings in one such lesion in the parotid. The smears were composed of a population of small spindly cells without distinctive cytologic features.

Intraductal Papilloma

These uncommon **cystic tumors** occur mainly in minor salivary glands but may sometimes affect the major glands as well (review in Brannon et al, 2001). The tumors form palpable nodules without any special features and the diagnosis is established by histology. The **cytologic findings** in two cases, one affecting the parotid and the other a submaxillary gland, were reported by Soofer and Tabbara (1999). In both cases, the aspiration yielded fluid, containing **orderly papillary clusters** of benign epithelial cells with oncocytic features, some showing **sebaceous differentiation**. The tissues in these cases disclosed thick-walled cysts with fibrovascular cores surfaced by benign, oncocytic epithelium with focal sebaceous differentiation. Clearly, these rare tumors closely resemble Warthin's tumor.

TABLE 32-4 PRINCIPAL CYTOLOGICAL FEATURES IN BASAL CELL ADENOMA

Cellular smears composed of small, uniform basaloid cells arranged in flat sheets and trabecula

Hyaline stroma, usually occurring at the periphery of cell groups but occasionally as a central globule

The parotid is the most likely site in elderly women

Differential Diagnosis

Adenoid cystic carcinoma, particularly of the solid type

Pleomorphic adenoma with basaloid proliferation

Capillary Hemangiomas

These proliferations of small blood vessels are usually observed in childhood as red or purple patches on the skin and very rarely, if ever, require cytologic or histologic diagnosis (Lack and Upton, 1988). A fortuitous case was reported by Koss et al (1992). The aspiration smear contained loosely structured bundles of **short spindly benign cells**.

MALIGNANT TUMORS

The principal malignant tumors of the salivary glands are listed in Table 32-5. Of these, mucoepidermoid carcinoma, adenoid cystic carcinoma, and acinic cell carcinoma are most common. The cytologic diagnosis of the various tumor types is sometimes very difficult and requires great attention to details and considerable experience, as is evident from the points of differential diagnosis in the tables.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common malignant neoplasm of salivary glands in adults (Evans, 1984) and the second most common in children (Flaitz, 2000). It is most frequently encountered in the parotid, but also occurs in minor salivary glands in the palate, retromolar zone, floor of mouth, and tongue.

Mucoepidermoid carcinoma is a tumor of duct origin. It is well-demarcated and painless at onset. In later stages, the tumor may infiltrate surrounding tissue, overlying skin, and metastasize to regional lymph nodes and distant organs (Spiro et al, 1978).

Histology

The tumors are composed of a mixture of **squamous (epidermoid), intermediate and mucus-producing cells** in various proportions. They are classified as low-, intermediate-, or high-grade, depending on the relative proportion of cystic mucinous component (low grade) versus solid epidermoid or intermediate cell component (high grade), presence of mitoses, neural invasion and necrosis (Hicks and Flaitz, 2000).

TABLE 32-5 PRINCIPAL MALIGNANT TUMORS OF THE SALIVARY GLANDS

Mucoepidermoid carcinoma

Adenoid cystic carcinoma

Acinic cell carcinoma

Epithelial-myoepithelial carcinoma

Salivary duct carcinoma

Oat cell and other endocrine carcinomas

Lymphoma

Metastatic tumors

P.1244

Low-grade mucoepidermoid carcinoma is slow growing, well demarcated, and painless. Cystic spaces within the tumor, and multiple papillary fronds projecting into them, are lined by columnar, mucus-producing epithelial cells, interspersed with large, usually well-differentiated squamous cells, occurring singly or in small clusters (Fig. 32-15A). The cysts' content consists of abundant thick mucoid material and usually a few mucus-producing cells, inflammatory cells, and cellular debris. Solid nests of polygonal intermediate epithelial cells may be present in the fibrous stroma of the tumor.

High-grade mucoepidermoid carcinoma is solid, grossly less well demarcated, and may have infiltrating margins. It is often painful and associated with facial nerve palsy. The tumor is composed predominantly of moderately to poorly differentiated squamous (epidermoid) and intermediate cancer cells, accompanied by scant mucus-producing cells (see Fig. 32-17D). There is often perineural invasion, tumor necrosis, and variable numbers of mitoses. Special stains may be needed to confirm the presence of mucus secretion in the cytoplasm of some of the squamous cells (see below) (Koss et al, 1992; Goode et al, 1998).

Intermediate-grade mucoepidermoid carcinoma combines the features of low-grade and high grade tumors, but the level of atypia in the squamous (epidermoid) component is moderate (Fig. 32-16B).

Figure 32-15 Mucoepidermoid carcinoma—low grade. A. Tissue section showing the mucinous and epidermoid components of the tumor. B, C. High magnification of mucicarmine-stained epidermoid cells to document the presence of mucus

(red) in the cytoplasm. (*D*: Courtesy Professor S. Woyke, Szczecin, Poland.)

Cytology

The needle aspirates of mucoepidermoid carcinoma may be classified as either low-grade or high-grade tumors, based on essentially the same criteria used for histologic grading. **Low-grade carcinomas often are difficult to recognize as malignant tumors. The smears usually consist of thick mucoid cyst fluid containing clusters of small, often rounded intermediate cells** with small, uniform nuclei and eosinophilic cytoplasm. Of critical diagnostic value is the presence of much **larger, mucus-producing cells with clear cytoplasm** attached to, or incorporated into, the clusters of intermediate cells (see Fig. 32-15B,C). Occasionally, somewhat larger cells of squamous lineage may be observed. Even though the cytoplasm of these cells is usually uniformly eosinophilic and opaque, it may sometimes show peripheral mucous vacuoles. Characteristically, the opaque cytoplasm of an occasional cell stains red with the **mucicarmine** stain, thus indicating the **presence of mucus** (see Fig. 32-15D). In spite of their sometimes deceptively benign appearance, these tumors are fully capable of invasion and metastases, sometimes many years after initial treatment.

P.1245

Figure 32-16 Intermediate-grade mucoepidermoid carcinoma. *A*. Aspiration smear with a cluster of intermediate cells and occasional, relatively small vacuolated, mucin-secreting cells. *B*. Histology of the same intermediate-grade mucoepidermoid carcinoma showing almost equal representation of mucinous and intermediate or epidermoid cells.

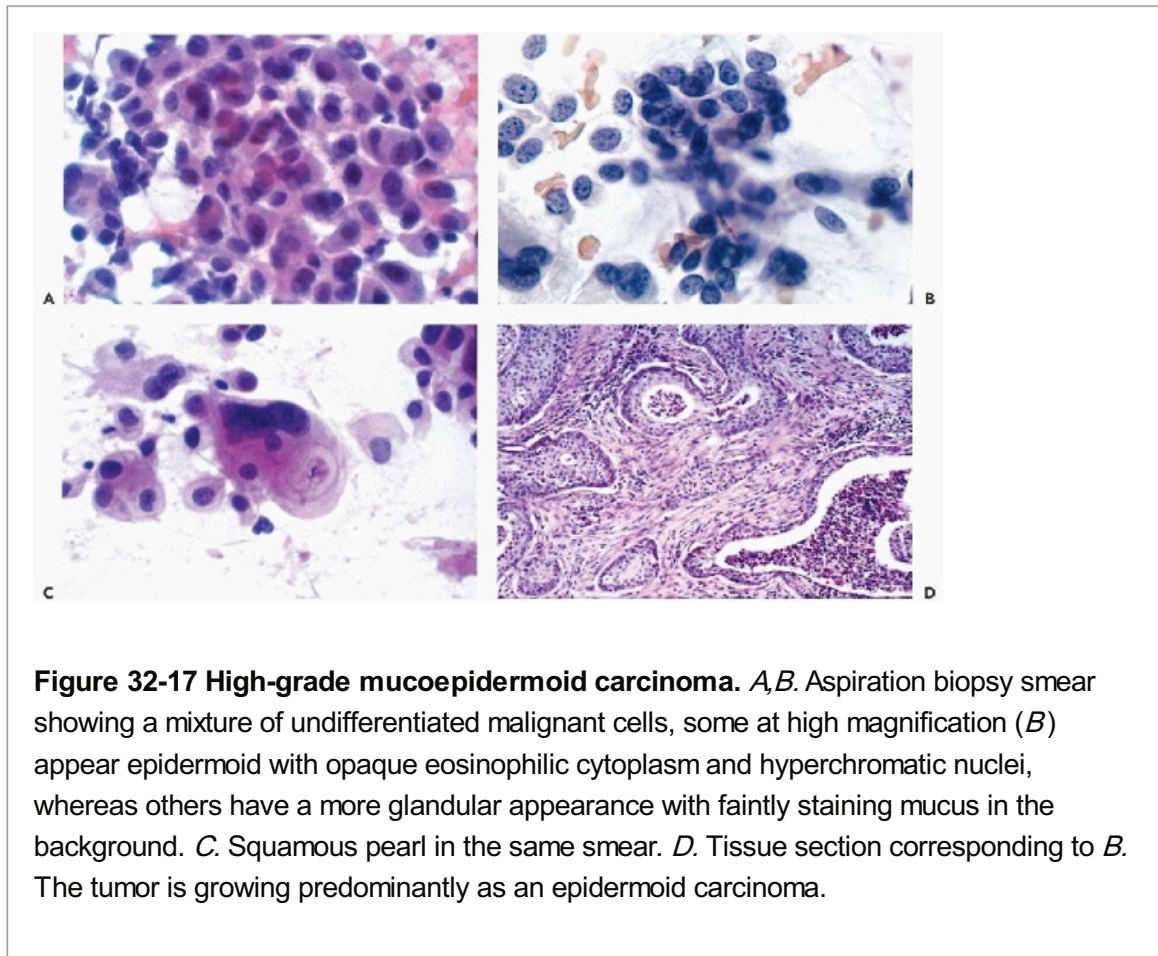

Aspirates of intermediate-grade mucoepidermoid carcinomas are more cellular than those of low-grade tumors, consisting of nonmucinous intermediate cells interspersed with mucin-secreting cells (Fig. 32-16A,B).

High-grade mucoepidermoid carcinomas are typically richly cellular and composed predominantly of intermediate, poorly differentiated and squamous cancer cells that may occur singly or in clusters. The sharply demarcated cells have homogeneous, basophilic, or eosinophilic cytoplasm in Papanicolaou stain (Fig. 32-17A). Variable cytoplasmic staining and sharp cell borders are seen in hematologic stains. The cells have large hyperchromatic

P.1246

nuclei (Fig. 32-17B). Scattered **mucus-producing vacuolated cells** are relatively few in

number. Occasionally, malignant **squamous “pearls”** may occur (Fig. 32-17C). Mitoses may be noted and there is often evidence of necrosis. **The mere presence of squamous cells, and particularly of a squamous pearl in a salivary gland aspirate, should raise suspicion of a mucoepidermoid carcinoma.**

The diagnosis of mucoepidermoid carcinoma is most **difficult for low-grade tumors** that yield scanty cellular aspirates containing usually only a few clusters of small, uniform intermediate tumor cells. Clues to this diagnosis are provided by knowledge that the aspirate was obtained from a cystic tumor (Klijanienko and Vielh, 1997) and by the mucoid, sparsely cellular nature of the smear. A careful search for a few mucus-producing cells is then imperative. In their absence, one must consider the possibility of a mucus retention cyst or mucocele. As previously noted, the presence of a persistent mass or thickening after aspiration of a cystic tumor, should suggest the possibility of a low-grade mucoepidermoid carcinoma.

The **differential diagnosis** of mucoepidermoid carcinoma includes the **extremely rare epidermoid inclusion cysts** and the equally rare **pleomorphic adenomas, with a dominant squamous component**. The latter, however, is accompanied by the customary stroma (see above). The clusters of malignant intermediate and/or squamous cells may be mistaken for an undifferentiated carcinoma or squamous cell carcinoma, but a careful search for mucous cells, the mucoid background, and the aid of special stains for mucus, help in establishing the correct diagnosis.

The principal features of mucoepidermoid carcinoma and its differential diagnosis are summarized in Table 32-6.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is a **highly malignant** but usually slow-growing, solid salivary gland tumor that is encountered more frequently in the submandibular and minor salivary glands than in the parotid. Adenoid cystic carcinomas also occur in the trachea, bronchus, esophagus, cervix, breast, and other organs (see appropriate chapters).

The first clinical manifestation of this tumor is usually a solid, mobile mass that is indistinguishable from a pleomorphic adenoma. With the passage of time, the tumor invades the surrounding structures. Perineural involvement is common, causing pain and fifth nerve palsy. The most characteristic feature of behavior of this tumor is local and destructive recurrences. Metastases may occur after several years, usually preceded by several local recurrences, and they frequently involve the lung and bone and, less often, lymph nodes (Haddad et al, 1995).

Histology

The tumor is composed of small basaloid cells with scant cytoplasm arranged in sheets or tubules around characteristic cystic spaces that contain homogeneous or fibrillary basement membrane material (Fig. 32-18A). The latter were originally described as “cylinders,” and the tumors were called “cylindromas.” There is considerable variability in the relative proportion of epithelial and acellular components from tumor to tumor. In some tumors, particularly late recurrences, the tumors are solid and the hyaline inclusions are very sparse. Penner et al (2002) noted that **c-kit** documented by immunostaining is expressed in these tumors. For further discussion of c-kit, see Chapter 24.

TABLE 32-6 PRINCIPAL CYTOLOGIC FEATURES OF MUCOEPIDERMOID CARCINOMA

Low grade

- Aspirate is rich in mucus, but usually contains few cells
- Mucus-producing cells have an abundant vacuolated cytoplasm
- Sparse clusters of intermediate cells wherein mucus can be documented
- Squamous cells, if present, are few with cytoplasmic vacuoles and cytoplasmic mucin.

Differential Diagnosis

- Mucinous cyst
- Pleomorphic adenoma with squamous component

Intermediate grade

- Deceptively benign-looking squamous cells with cytoplasmic mucin

Rare mucus-producing cells

High grade

Abundant clearly malignant cells of epidermoid or keratinized type

Mucus production is scant and may be difficult to document without special stains.

Differential Diagnosis

Epidermoid inclusion cysts

Squamous carcinoma (primary or metastatic)

Cytology

Aspirates from adenoid cystic carcinoma usually yield moderately cellular smears with two components: **epithelial cells** and **acellular basement** membrane material, the latter appearing as **homogeneous spherical structures that are diagnostic and nearly unique to this tumor**.

The epithelial cells are relatively small with basaloid appearance and scant amounts of cytoplasm; they may have small, but clearly visible nucleoli. For the most part, they are arranged in **cohesive, often spherical, or tri-dimensional globoid clusters** of various sizes, surrounded by loose epithelial cells, usually devoid of cytoplasm (Fig. 32-18B). **The key to the diagnosis is the identification of tumor cell clusters with a central core of homogeneous basement membrane substance**, corresponding to the acellular component

P.1247

of the tumor (Fig. 32-18B). In exceptional cases, numerous cores will be observed in one area of the smear (Fig. 32-18C). Finding the central core may require careful examination of several clusters of cells. In Papanicolaou and hematoxylin-eosin-stained material, **the cores** may be **eosinophilic, but very often are transparent** and visualized only by careful up-and-down focusing of the microscope. The cores stain better with polychrome stains, such as Giemsa, Diff-Quik, and alcian blue (Fig. 32-18D). In aspirates with abundant acellular material, one may find hyaline cylinders or barrel-shaped structures accompanying, or surrounded by, tumor cells in palisade-like arrangement (Fig. 32-18C).

Figure 32-18 Adenoid cystic carcinoma. *A.* Histologic section showing the characteristic cribriform configuration of the tumor with small, dark, basal epithelial cells lining cystic spaces filled with homogeneous material. *B.* Thin-needle aspirate is composed of sharply demarcated spherical clusters of small, basaloid cells containing globoid cystic spaces. *C.* The basement membrane hyaline material is well demonstrated here, but is best brought out by polychrome stains (Diff-Quik), as in *D*, in which the globoid masses, lying in close association with basaloid cells, take on a bright magenta hue.

Occasionally, very large fragments of tissue composed of several aggregates of tumor cells are aspirated. These large aggregates have a lobulated appearance caused by darker “grooves.” The central core of homogeneous substance usually can be seen within these lobules by focusing up and down (Koss et al, 1992; Nagel et al, 1999).

Smears from poorly differentiated adenoid cystic carcinomas, which are composed mostly of solid sheets of tumor cells, may lack the hyaline core material; hence, the precise determination of tumor type becomes difficult. However, clustering in spherical aggregates of the small tumor cells, some of which have somewhat enlarged nuclei with coarse chromatin pattern and prominent nucleoli, facilitates the correct diagnosis. The differential diagnosis includes basal cell adenoma, cellular pleomorphic adenoma that may contain many small basaloid cells (Klijanienko and Vielh, 1997), and the very rare endocrine type of carcinoma (see below).

Dermal eccrine cylindromas, benign tumors of sweat glands, may be mistaken for adenoid cystic carcinomas of the parotid. Bondeson et al (1983) compared the aspiration biopsy pattern of these two tumors with vastly different behavior, and concluded that they cannot be separated on cytologic grounds. Since eccrine cylindroma is a mobile lesion of the dermis, the clinical presentation is essential in the differential diagnosis.

The principal features of adenoid cystic carcinoma and its differential diagnosis are summarized in Table 32-7.

Acinic Cell Carcinoma

Acinic cell carcinoma constitutes about 3% of malignant salivary gland tumors. It is a slow-growing, sometimes bilateral, low-grade malignant tumor arising most often in the

parotid gland. It may rarely arise in the submandibular gland, and is quite rare in minor salivary glands. This is the most common malignant salivary gland tumor in **children and adolescents**. The prognosis of the tumor depends on stage at discovery. Superficial tumors, particularly those seen in young patients, fare quite well after surgical treatment (Spiro et al, 1978). Still, local recurrence after excision (Timon et al, 1995), metastases to regional lymph nodes, and distant metastases to lungs and bone have been observed despite the seemingly indolent nature of this tumor.

TABLE 32-7 PRINCIPAL CYTOLOGICAL FEATURES OF ADENOID CYSTIC CARCINOMA

Numerous spherical or three-dimensional tumor fragments composed of small monotonous cancer cells

Central cores of hyaline material

Dispersed tumor cells with uniform dark nuclei and small, but visible, nucleoli in poorly differentiated tumors, hyaline cores may be absent, but the tumor cells display crowding and sometimes marked nuclear abnormalities facilitating the diagnosis of a malignant tumor.

Differential Diagnosis

Basal cell adenoma, dermal eccrine cylindroma

When the central core of hyaline material is absent:

Basal cell adenoma/adenocarcinoma

Cellular pleomorphic adenoma

Small cell endocrine carcinoma

Basal cell carcinoma of skin

Figure 32-19 Acinic cell carcinoma. *A* Histologic section showing a solid mass of malignant acini, lined by cells with abundant basophilic, granular cytoplasm. There are no ducts present. *B, C* Thin-needle aspirate reveals cohesive clusters and loose tumor cells that individually may resemble normal acinar cells, but are much larger. Further, the architecture of the salivary gland is lost (compare with Fig. 32-4), and there are no ducts or fat. The tumor cells, best seen at the periphery of the clusters, are polyhedral with abundant pale or basophilic granular cytoplasm and small nuclei. *D* There are many stripped nuclei with cytoplasmic debris in the background.

Histology

The tumor cells, although much larger, closely resemble the serous acinar cells of the normal parotid. The cells are cuboidal or polyhedral and are arranged in cords or acini separated by scanty stroma (Spiro et al, 1978). They have abundant, clear or basophilic, finely granular cytoplasm and uniform, small eccentric nuclei with fine chromatin pattern, and tiny nucleoli (Fig. 32-19A). Some tumors are characterized by abundant lymphocytic stroma. Several **histologic variants** have been described, among them cystic, follicular, and papillary types. None of these patterns appears to be of prognostic value.

P.1249

Cytology

Aspirate smears from the classic form of acinic cell carcinoma are usually rich in cells. The cells are frequently arranged in irregular **clusters forming linear, acinar, and glandular** structures, accompanied by a visible network of capillaries. The individual **tumor cells** are much larger than their normal counterpart in serous acini and they display marked variation in size and shape (Palma et al, 1985). They have pale or moderately granular cytoplasm and eccentric, small nuclei, sometimes with visible nucleoli (Fig. 32-19B,C) (Nagel et al, 1997). Abundant “naked” tumor cell nuclei and bluish cytoplasmic granules of destroyed tumor cells are present in the background (Fig. 32-19D) (Koss et al, 1992; Klijanienko and Vielh, 1997). Lymphocytes may be present.

Smears from the uncommon **poorly differentiated acinic cell carcinomas** yield classic

cancer cells that have large, dark nuclei and prominent nucleoli but lack the cytoplasmic granules of differentiated acinar cells. It is easy to recognize the malignant nature of the tumor cells, but it may be difficult to predict its histologic type. Layfield and Glasgow (1993) also pointed out that a component of “**clear cells**” may be observed in this or other lesions of salivary glands, such as clear cell oncocytoma, and in metastatic renal carcinoma. **Psammoma bodies** have occasionally been found in acinic cell carcinoma (Bottles and Löwhagen, 1985). In our experience, however, none of these uncommon happenings obscure the cytologic pattern of a classical acinic cell carcinoma.

Aspirates from the **papillary cystic variant of acinic cell carcinoma** may contain abundant necrotic material in combination with well-preserved tumor cells forming papillary clusters (Koss et al, 1992). The principal features of acinic cell carcinoma and its differential diagnosis are summarized in Table 32-8.

Malignant Tumors Ex-Pleomorphic Adenoma

Cancer can occasionally arise in a pleomorphic adenoma. These tumors usually occur in the salivary glands of **elderly patients** who often give a history of a palpable nodule of many years' duration and recent rapid growth (Gerugthy et al, 1969). Similar tumors may occur in lacrimal glands (see Chap. 41). The diagnosis of this relatively uncommon tumor is based on the **synchronous presence of elements of a pleomorphic adenoma and a malignant tumor that is usually a carcinoma, but sometimes a chondrosarcoma** (Koss et al, 1992), or **rhabdomyosarcoma** (Gandour-Edwards et al, 1994). Carcinomas may be of various types and varying degrees of differentiation (LiVolsi and Perzin, 1977). Ellis and Auclair (1996) listed hypercellularity, capsule violation, hyalinization, necrosis, and cellular anaplasia as necessary histologic features for the diagnosis. Gerugthy et al (1996) observed **psammoma bodies** in 9 of 25 cases. The prognosis is poor.

TABLE 32-8 PRINCIPAL CYTOLOGICAL FEATURES IN ACINIC CELL CARCINOMA

Abundant sheets and clusters of basophilic cells of variable sizes with bland nuclei

Granular or clear cytoplasm, and eccentric nuclei

Numerous stripped spherical and relatively bland nuclei with small nucleoli

Differential Diagnosis

Normal salivary gland tissue

Low-grade mucoepidermoid carcinoma

Cytology

As in histologic material, the precise cytologic diagnosis requires the identification of components of the pleomorphic adenoma and of the malignant tumor derived therefrom. This

happens rarely but such cases have been reported (Geisinger et al, 1985; Koss et al, 1992). In some cases, the **cytologic pattern of pleomorphic adenoma may obscure the presence of a malignant tumor** (Jacobs, 1993). **More often, however, the pattern of a malignant tumor** will obscure the presence of a pleomorphic adenoma (Eneroth and Zajicek, 1966; Zajicek and Eneroth, 1970; Pitman, 1995; Viguer et al, 1997; Heintz et al, 1998). An example of the latter is shown in Figure 32-20.

The problems with the cytologic recognition of this tumor type were illustrated by Klijanencko et al (1999b) who published a series of 26 such cases comprising 17 cases of high-grade and 9 of low-grade carcinomas. The cytologic diagnosis of cancer could be established in only 50% of the 26 cases, mostly for high-grade tumors. In 10 cases, the presence of a malignant mixed tumor was obscured by the pattern of pleomorphic adenoma. It is of note that similar malignant tumors of the **lacrimal glands may metastasize to the salivary glands** and vice versa (Klijanienko et al, 1999).

Basal Cell Adenocarcinoma

Basal cell adenocarcinoma accounts for approximately 3% of malignant salivary gland tumors. It is a low-grade malignant tumor more commonly encountered in the parotid. Histologically, it is similar to basal cell adenoma but has an infiltrative growth pattern (Fig. 32-21A).

Cytology

Smears of basal cell adenocarcinoma are strikingly similar to basal cell adenoma. Nuclear atypia is more prominent, but definitive diagnosis by FNA is difficult (Fig. 32-21B,C). Klijanienko et al (1999a) reported on 15 basal cell tumors and were able to recognize four of them as malignant because of the presence of three-dimensional cell clusters with some degree of nuclear atypia. However, other observers experienced serious difficulties in separating **basal cell carcinoma**, not only from the **benign basal cell adenoma**, but also from **solid adenoid cystic carcinoma** (Hood et al, 1983;

P.1250

Stanley, 1996). Moroz et al (1996) noted that the **DNA ploidy measurements are not helpful** as all these tumors are diploid. To this list of differential diagnoses, we would add the very rare **small-cell endocrine carcinoma and malignant lymphoma** (see below). In the absence of features characteristic of other specific tumor types, one might consider this rare entity. However, for most tumors of the salivary glands, composed of small cells without special morphologic features such as the hyaline cores of adenoid cystic carcinoma, it is best not to try to establish a definitive cytologic classification and request a histologic examination of the tumor.

Figure 32-20 Carcinoma ex pleomorphic adenoma (malignant mixed tumor). *A.* Aspiration smear showing a cluster of cancer cells. The nature of the tumor could not be determined in the smear. *B.* Carcinoma originating in pleomorphic adenoma; the latter is not shown.

Figure 32-21 Basal cell adenocarcinoma. *A.* The histologic appearance closely resembles that of basal cell adenoma, from which it is distinguished by invasion into adjacent tissues. Note the peripheral palisade arrangement of basal cells. *B,C.* The thin-needle aspirate shows cohesive groups of small basaloid cells and is indistinguishable from that of basal cell adenoma. Compare with Figure 32-14.

Polymorphous Low-Grade Adenocarcinoma (PLGA)

This uncommon tumor occurs almost exclusively in **minor salivary glands**, particularly in the palate and elsewhere in the oral cavity (Ritland et al, 1993; Castle et al, 1999). It is more common in women and in African Americans above

P.1251

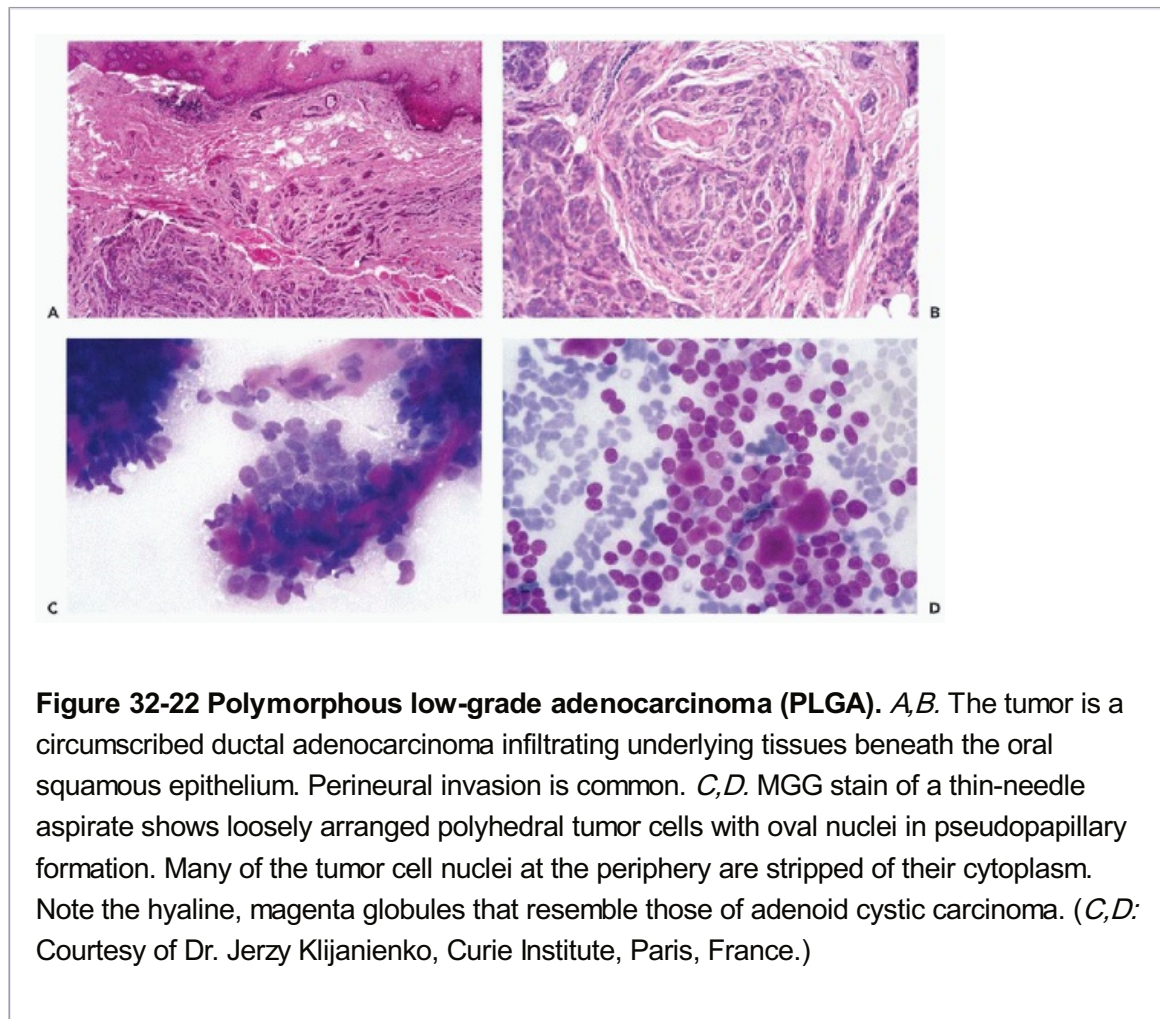

50 years of age. The patients present with a **circumscribed asymptomatic tumor nodule** that is usually encapsulated but may have an infiltrative border.

Histology

In histologic sections, the tumor is composed of **medium-sized eosinophilic cells with cuboidal, columnar, or spindle cell shape and monotonous nuclei with fine chromatin** (Pérez-Ordoñez et al, 1998). The tumor displays a variety of growth patterns, hence the name. Combinations of **cribriform, solid, or tubular growth patterns**, and transition from one type to another, are seen within the same tumor (Fig. 32-22A,B). The stroma varies from mucoid to hyaline. Tyrosine-rich crystalloids have been reported (Raubenheimer et al, 1990). Perineural invasion and infiltration into adjacent bone are frequent. Metastases to distant organs, although infrequent, have been observed.

Cytology

Aspirates usually yield cellular smears. The cells are **cuboidal to columnar** with uniform, round, or oval nuclei and scant cytoplasm. They are arranged in **clusters or sheets of cells, or in papillae** that may have a **central core of hyaline, thus mimicking adenoid cystic carcinoma** (Klijanienko and Vielh, 1998; Gibbons et al, 1999). Acellular material, in the form of magenta-colored globules (in a hematologic stain) and mucoid substance, are common in the background. There is little pleomorphism, no necrosis, and mitoses are absent or rare (Fig. 32-22C,D) (Evans, 1984; Klijanienko and Vielh, 1998).

The **differential diagnosis** includes adenoid cystic carcinoma, epithelial myoepithelial carcinoma, papillary cystadenocarcinoma, and benign pleomorphic adenoma. It may be impossible in some cases to distinguish polymorphous low-grade adenocarcinoma from adenoid cystic carcinoma on smears alone; however, contrary to adenoid cystic carcinoma, the polymorphous low-grade adenocarcinoma is extremely rare in major salivary glands. Penner et al (2002) recently reported that **c-kit is expressed in all adenoid cystic carcinomas** but only in about half of the polymorphous low-grade adenocarcinomas. Whether this, or other differences in antigenic expression, will prove of value in cytologic samples remains to be seen. The presence of chondromyxoid stroma with spindle and plasmacytoid cells supports the diagnosis of a pleomorphic adenoma (Watanabe et al, 1999). The principal features of polymorphous low-grade

adenocarcinoma and its differential diagnosis are summarized in Table 32-9.

TABLE 32-9 PRINCIPAL CYTOLOGICAL FEATURES IN POLYMORPHOUS LOW-GRADE ADENOCARCINOMA

Aspirate from tumors in palate or oral cavity

Cellular smears arranged in flat sheets or papillae, often with hyaline inclusions

Cells are cuboidal or columnar with bland nuclei.

There is no necrosis and mitoses are absent.

Differential Diagnosis

Adenoid cystic carcinoma

Pleomorphic adenoma

Papillary cystadenocarcinoma

Epithelial-Myoepithelial Carcinoma

This is a rare carcinoma, predominantly of **major salivary glands**, usually occurring in the parotid. The patients are commonly older women, frequently in their 60s, who present with a **painless firm mass**. The tumor is usually well circumscribed and solitary; it is composed of well-defined **tubules with double cell lining**. The inner epithelial cell layer is basaloid or cuboidal and the outer layer is composed of ovoid myoepithelial cells with abundant clear cytoplasm (Brocheriou et al, 1991). A well-developed basement membrane surrounds most of the tubules (Fig. 32-23A,B) (Klijanienko and Vielh, 1998c).

Cytology

Aspirates of this tumor are moderately cellular. The smears are composed of **two types of cells**: the larger, uniform cuboidal epithelial cells, often arranged in gland-like clusters (see Fig. 32-22C) and smaller, spindly myoepithelial cells, usually seen as “bipolar” spindly nuclei (see Fig. 32-22D). The nuclei of the epithelial cells are bland and spherical, with only slight variability in sizes. **Hyaline basal material** is noted among epithelial groups (Carrillo et al, 1990; Arora et al, 1990; Koss et al, 1992).

The differential diagnosis includes adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma, and pleomorphic adenoma. The presence of **two types of cells** supports the diagnosis of epithelial-myoepithelial carcinoma, rather than pleomorphic adenoma (Stewart et al, 1997). The principal features of epithelial-myoepithelial carcinoma and its differential diagnosis are summarized in Table 32-10.

Myoepithelial Carcinoma

These tumors are more common in the breast (see Chap. 29) and are exceedingly uncommon in the salivary glands, nearly always occurring in the parotid. The tumors, composed of **spindly or polygonal cancer cells forming nodules**, resemble **pleomorphic adenoma** because of stroma of **mucoïd or hyaline matrix** (Savera et al, 2000). Therefore, such tumors are sometimes **mistaken for malignant or benign mixed tumors**. Another important aspect of some of these tumors is the quasi benign appearance of the tumor cells, in spite of the tendency of the tumor to recur and metastasize. The myoepithelial origin of the tumor has been documented by electron microscopy and immunochemistry.

TABLE 32-10 PRINCIPAL CYTOLOGICAL FEATURES IN EPITHELIAL-MYOEPITHELIAL CARCINOMA

Aspirates from major salivary glands

Two families of cells: the larger epithelial cells arranged in tubular or acinar clusters and the smaller myoepithelial cells seen mainly as “bipolar” spindly nuclei

Minimal nuclear atypia

Differential Diagnosis

Adenocystic carcinoma

Pleomorphic adenoma

Polymorphous low-grade adenocarcinoma

Cytology

To our knowledge, there are only two reports on cytology of the myoepithelial carcinoma (DiPalma et al, 1996; Chhieng and Paulino, 2002). Not surprisingly, some of the five tumors reported by DiPalma et al were thought to represent recurrent pleomorphic adenomas. Only two of the five tumors were cytologically malignant, in keeping with the histologic division into low-grade and high-grade tumors (Savera et al, 2000).

In FNA smears, the major finding was the **variations in cell shape**. Round, oval, polygonal and plasma cell-like cells were observed. Nuclear cytoplasmic inclusions and nuclear grooves were in evidence. Chhieng and Paulino (2002) reported three bona fide cases, two of which were diagnosed as malignant spindle-cell neoplasm and one as pleomorphic adenoma. It is obvious that the precise recognition of this tumor in salivary glands is fraught with difficulties that may require ample tissue samples for accurate classification.

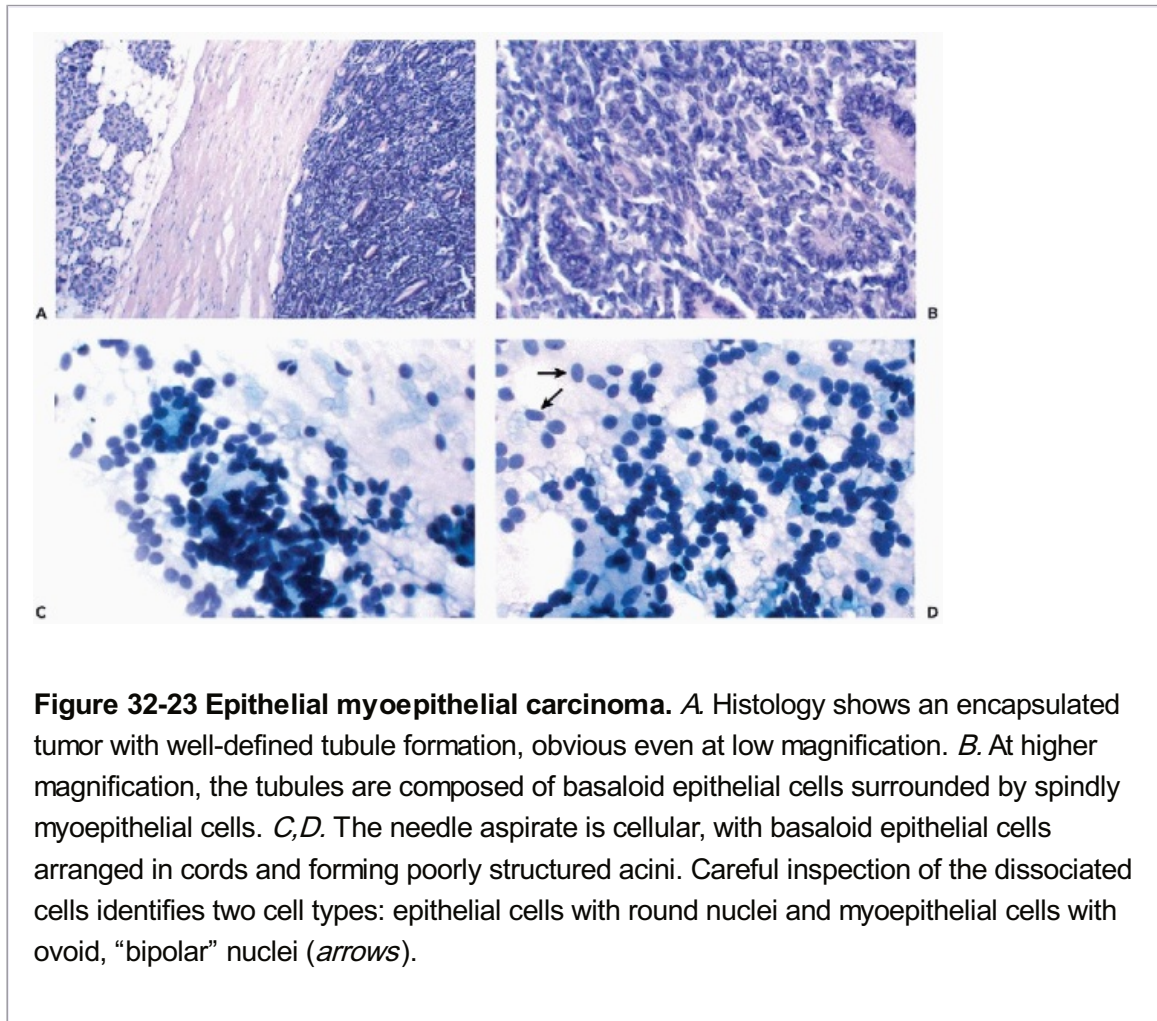

Salivary Gland Duct Carcinoma

Duct carcinomas of salivary gland are relatively uncommon highly malignant neoplasms with marked **male predominance** (Brandwein et al, 1990). Patients are usually in their 50s and

present with a rapidly growing mass of recent onset. The mass may be painful and is commonly fluctuant because of necrosis. The parotid is the most common site. A

P.1253

case of **intraductal carcinoma** of oral cavity in a woman was described by Cheuk et al (2004).

This tumor **resembles ductal carcinoma of the breast**. It is multifocal with cribriform, comedo, papillary, and intraductal patterns. The infiltrative component displays marked desmoplastic reaction with variable hyalinization of stroma. Tumor cells have abundant pale pink cytoplasm and large pleomorphic nuclei with coarse chromatin and abundant mitoses. Necrosis, perineural invasion, and tumor emboli are frequently seen (Fig. 32-24A).

Cytology

Aspirates of salivary gland duct carcinoma are usually moderately cellular. The **tumor cells are large and anaplastic**, and arranged in **cohesive clusters, sheets, or papillary fragments**. Necrosis is a prominent feature (Fig. 32-24B,C) (Klijanienko and Vielh, 1998). Stanley et al (1995) pointed out that similar cell patterns may be observed in **other high-grade primary tumors of salivary glands and in metastatic carcinomas**. In keeping with this observation, several diagnostic errors were reported by Khurana et al (1997). The principal features of salivary duct carcinoma and its differential diagnosis are summarized in Table 32-11.

Squamous Carcinoma

Squamous cell carcinomas account for about 4% of the tumors of major salivary glands. As with

mucoepidermoid carcinomas, the pathogenesis is based on the potential of benign or malignant ductal epithelium to undergo squamous metaplasia. Whether pure squamous carcinomas actually are a unique entity or represent squamous differentiation

P.1254

of mucoepidermoid carcinoma can be debated, but it is immaterial for all practical purposes.

TABLE 32-11 PRINCIPAL CYTOLOGICAL FEATURES OF SALIVARY DUCT CARCINOMA

Moderate to markedly anaplastic cancer cells in a major salivary gland in an elderly patient (particularly men)

Necrosis in background

Differential Diagnosis

Metastatic carcinoma

High-grade mucoepidermoid carcinoma or other high-grade salivary gland cancers

Figure 32-24 Salivary duct carcinoma. *A* Histologic appearance closely resembles comedocarcinoma of breast. *B* The needle aspirate is cellular, and composed of noncohesive pleomorphic tumor cells. *C* At higher magnification, there is great variation in cellular and nuclear size; tumor cells have a moderate amount of cytoplasm, resembling a needle aspirate of duct carcinoma of breast. (*B,C*: MGG stain.) (Case courtesy of Dr. Jerzy Klijanienko, Curie Institute, Paris, France.)

Cytology

The diagnosis can be established if an adequate aspirate of salivary gland tumor contains **only cells of squamous carcinoma** without admixture of either mucus or glandular epithelium. The cytology of these tumors is described in detail in several chapters, mainly 11 and 20.

Metastatic squamous carcinoma from another site must be excluded and this cannot be determined from the study of the aspirate (Klijanienko and Vielh, 1998). Thus, in reporting the presence of squamous carcinoma in a salivary gland aspirate, it must be made clear that clinical information is needed to exclude a metastasis or origin in a high-grade mucoepidermoid carcinoma.

Undifferentiated Carcinoma

If the FNA smears of a salivary gland tumor contain cancer cells without evidence of differentiation, one may suggest the diagnosis of an undifferentiated malignant tumor, recognizing that in most cases a formal biopsy or histologic examination of the resected tumor may allow a more specific classification. If the cytologic pattern is that of a highly anaplastic malignant tumor, the **possibility of a metastatic malignant melanoma or anaplastic carcinoma should be considered.**

Mucinous (Colloid) Adenocarcinoma

Mucinous adenocarcinoma of salivary glands is a very uncommon lesion. It **resembles colloid carcinomas of the breast and colon**, described in Chapters 24 and 29. The tumor is composed of **papillary aggregates of well-differentiated tumor cells floating in lakes of mucus** (Osaki et al, 1990).

To our knowledge, there is but one report on cytology of this tumor by Tambouret et al (1999). The findings were very similar to those described in the much more common colloid carcinoma of the breast (see Chap. 29).

Papillary Carcinomas

These uncommon tumors occur mainly in the **minor salivary glands** and may be subclassified as **low-grade papillary adenocarcinomas** and **papillary cystadenocarcinomas** (Spiro et al, 1973). The difference between these two tumor types is negligible.

Cytology

In our experience, the cytologic pattern of these tumors resembles other similar tumors in other organs, such as the ovary or the breast. Epithelial cells with **varying degrees of nuclear abnormality** form **oval or spherical multilayered papillary clusters**. An assortment of cancer cells, occurring singly or in small clusters, is observed in the background, which usually also shows some **evidence of necrosis** and sometimes the presence of **macrophages**. Similar findings were reported by Pisharodi (1997) and by Klijanienko and Viehl (1998).

P.1255

The latter authors also pointed out that the smears from a **polymorphous low-grade adenocarcinoma** may have a similar cytologic presentation, but also contain stromal fragments and hyaline deposits, thus resembling pleomorphic adenomas and adenoid cystic carcinomas.

Lymphoepithelial Carcinoma

These tumors of salivary glands occur mainly in Chinese and Inuit (Eskimo) patients and are

similar to nasopharyngeal carcinomas of the same type (Safneck et al, 1997). The tumors are composed of **sheets and strands of malignant epithelial cells surrounded by a lymphocyte-rich stroma** (see Chap. 21).

There are a few reports of the cytologic presentation of these tumors in FNA smears of salivary glands.

Thompson et al (1994) reported a case of this tumor occurring in a 42-year-old Caucasian woman. The smear pattern, both in the primary tumor and in the lymph node metastases, was identical to that of nasopharyngeal tumor and consisted of **sheets of large epithelial cancer cells** surrounded by **aggregates of lymphocytes**. Safneck et al (1997) described similar findings in five primary and two metastatic tumors. We have not seen a case of our own.

This cytologic presentation, particularly in Chinese or Inuit patients, is suggestive of the lymphoepithelial carcinoma of salivary glands, **provided that the much more common metastatic nasopharyngeal carcinoma has been ruled out**.

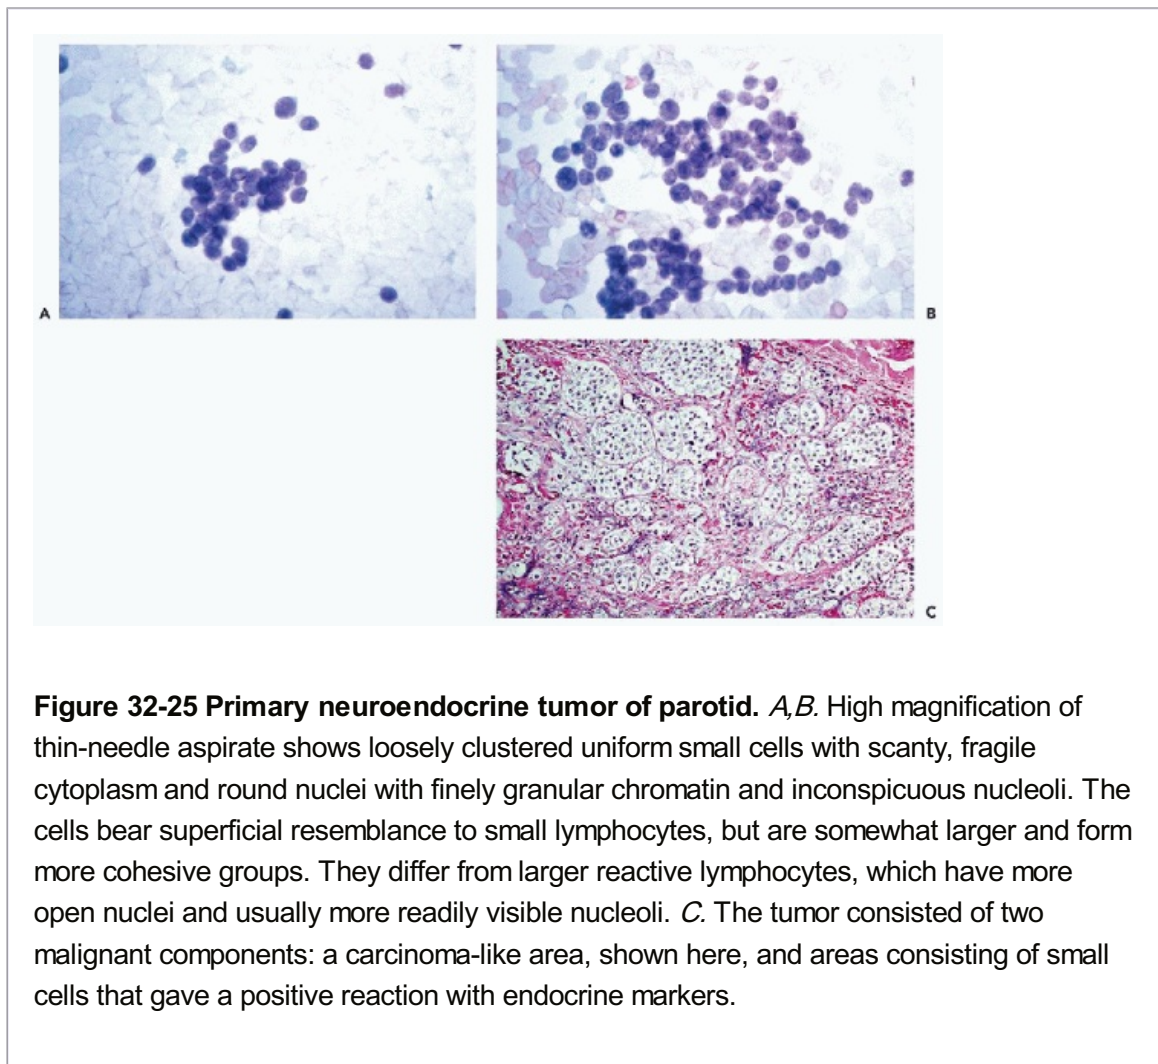

Figure 32-25 Primary neuroendocrine tumor of parotid. *A,B.* High magnification of thin-needle aspirate shows loosely clustered uniform small cells with scanty, fragile cytoplasm and round nuclei with finely granular chromatin and inconspicuous nucleoli. The cells bear superficial resemblance to small lymphocytes, but are somewhat larger and form more cohesive groups. They differ from larger reactive lymphocytes, which have more open nuclei and usually more readily visible nucleoli. *C.* The tumor consisted of two malignant components: a carcinoma-like area, shown here, and areas consisting of small cells that gave a positive reaction with endocrine markers.

Oat Cell and Other Endocrine Carcinomas

Small-cell (oat cell) carcinoma of minor salivary gland was first described by Koss et al in 1972. Several examples of this rare tumor have since been reported, both in minor and major salivary glands, and their endocrine features have been confirmed by the presence of dense core endocrine granules in the cytoplasm.

Information on the aspiration biopsy of these uncommon tumors is scarce. Mair et al (1989) and Cameron et al (1990) each reported one such case with cytologic findings akin to those of an oat cell carcinoma of the lung.

We observed an unusual **endocrine carcinoma of the parotid** in which there were **two morphologic components: a small-cell component, as in oat cell carcinoma, and a population of large polyhedral epithelial cells with clear cytoplasm arranged in nests** (Fig. 32-25C). The epithelial cells gave a strongly positive reaction with chromogranin, confirming the endocrine nature of the tumor. An **aspiration biopsy smear disclosed only small cancer cells** with very scanty cytoplasm and spherical to oval nuclei (Fig. 32-25A,B). Nucleoli were not visible. The cells formed compact clusters or were dispersed. The large clear cells were not seen in the aspirate, presumably because of differences in cohesion of the two tumor cell components.

Lymphoid Lesions

Lesions of lymphocytes affecting the salivary glands may be **benign** or **malignant**. It is not always clear whether the

P.1256

cells of origin reside in the organized lymphoid tissue, such as intraparotid lymph nodes, or from more diffuse lymphocytic infiltration.

Some of the **benign lesions** associated with **lymphocytic proliferations** were discussed in the first part of this chapter. Of special interest here are **benign lymphoepithelial cysts** occurring mainly in HIV-infected drug users. Benign **lymphoepithelial lesions** may also occur in patients with **Sjögren's syndrome**. The patients with the latter lesions have a significantly **increased risk for the development of malignant lymphoma** (Harris, 1999), some of which have an indolent course over a period of many years.

Castleman's disease of the parotid was reported by Panayiotides et al (1998).

Malignant Lymphoma

Malignant lymphomas account for 2% to 5% of all salivary gland tumors (Glesson et al, 1986). The parotid is most frequently involved (70%), followed by the submandibular gland (25%). The average age for patients with lymphoma is 65 years. Approximately 10% to 20% have symptoms associated with Sjögren's syndrome (i.e., lymphoepithelial sialoadenitis) (Harris, 1999).

The following three types of lymphoma are the most common in the salivary gland:

- **Marginal Zone B-cell lymphoma (MALT lymphoma)**, which typically arises in patients with lymphoepithelial sialoadenitis
- **Follicular lymphoma**
- **Diffuse large B-cell lymphoma**, an aggressive form of lymphoma that diffusely involves the parenchyma of salivary gland tissue

Combined cytology and immunophenotyping by flow cytometry may prove adequate for preliminary diagnosis, but biopsy is generally needed for confirmation (Cha et al, 1997). Cytologic presentation of these tumors is discussed in greater detail in Chapter 31. Of note is the presence of **crystal-storing macrophages in a case of MALT lymphoma of parotid** reported by Llobet et al (1997). This feature appears to be unique to salivary gland lymphoma.

VERY RARE TUMORS

Occasional reports of exceptionally rare tumors of the salivary glands, some with aspiration cytology, have been published.

Thus, **benign and malignant tumors of striated muscle** may affect salivary glands. A case of **rhabdomyoma of the palate**, described by Vuong et al (1990), was recognized by the presence of mature muscle cells with cytoplasmic cross-striations.

Cases of **alveolar rhabdomyosarcoma of the parotid** were reported by De et al (2001) and Valencerina-Gopez et al (2001). In the latter case, the tumor was not recognized as such on FNA smears.

Embryonal rhabdomyosarcoma of salivary glands is usually observed in children (Rogers et al, 1994; Kapadia et al, 1996). The cytology of three cases of **primary embryonal rhabdomyosarcoma of the parotid** in children aged 3 to 7 were reported by Salamao et al (1998). These authors reported the presence of different populations of malignant cells in each case, ranging from small, round cell tumor to spindly tumor cells.

We observed a child with **embryonal rhabdomyosarcoma of the inner ear**, masquerading as a salivary gland tumor. The cytology of a recurrent tumor disclosed small cancer cells without specific features.

In a group of seven **pediatric and adolescent patients**, Mathew and Ali (1997), observed an extraordinary assortment of benign and malignant lesions ranging from lymphoepithelial cyst, a **pilomatrixoma**, to several carcinomas and one case each of rhabdomyosarcoma and **Ewing's tumor**.

A **true carcinosarcoma** of the parotid, composed of **squamous carcinoma** and malignant fibrous histiocytoma, was reported by Latkovich and Johnson (1998).

Tumors of nerve (**schwannomas**), connective tissue (**fibromas and fibrosarcomas**) or synovia (**synoviomias**) may be observed, either within the salivary glands or their immediate vicinity. A case of **nodular fasciitis** involving the parotid was reported by Abendroth and Fraenhoffer (1995). These tumors are described in Chapter 35.

Metastatic Tumors

Malignant tumors arising outside the salivary glands can involve them by direct extension or by metastasis via lymphatic or hematogenous routes. Metastatic tumors to the salivary glands accounted for 10% of all malignant salivary gland tumors at the Armed Forces Institute of Pathology (Ellis and Auclair, 1996). The parotid gland, because of its intimate relationship with the lymphatic system, is the most common salivary gland site of metastases. The submandibular and sublingual glands are seldom involved except by direct extension from carcinoma of the floor of the mouth.

Squamous carcinomas and melanomas of the head and neck are the most common malignant tumors to metastasize to the parotid (Lussier et al, 2000). Carcinomas of lung, breast, and kidney reach the parotid by hematogenous routes. Metastatic neoplasms to the parotid have a very poor prognosis with an overall 5-year survival rate estimated at 12.5% (Stanley et al, 1995).

In patients who have a parotid tumor mass and known past or present history of malignant tumor at another site, the possibility of metastasis must always be considered. We have encountered several such cases, including a **melanoma** (Fig. 32-26A,B) and a **renal cell**

carcinoma (Fig. 32-27A,B). We have also observed a case of **large B-cell type lymphoma** invading the parotid gland (Fig. 32-28A,B). Awareness of clinical history, review of previous pathological material, as well as the possible use of immunohistochemical staining, are most helpful in confirming or excluding metastatic tumor (Zhang, et al, 2000). However, except for carcinomas invading from an adjacent site, a tumor mass in either major or minor salivary gland is still most likely to be a primary tumor.

P.1257

Figure 32-26 Metastatic melanoma to intraparotid lymph node. *A.* Whole mount of the lymph node, partially replaced by the pigmented tumor. *B.* Needle aspirate of the same tumor at high magnification showing dissociated malignant cells with relatively large nuclei and nucleoli. Intracytoplasmic pigment is seen in some of the tumor cells.

ACCURACY OF CYTOLOGIC DIAGNOSIS OF SALIVARY GLAND LESIONS

The accuracy of salivary gland FNA in the diagnosis of malignant tumor is generally comparable to that of frozen section (Chan et al, 1992). Sensitivity ranges from 62% to 98%, specificity ranges from 85% to 100%, and overall accuracy ranges from 87% to 97%. Caution should be used in comparing earlier with more recent data because the earlier studies used Foote and Frazell's (1954) classification, whereas the more recent studies use the 1991 classification of the World Health Organization (Seifert and Sobin, 1992). The two classifications are not identical. Sensitivity, specificity, and accuracy of recently reported studies of salivary gland tumor diagnosis by fine-needle aspiration are summarized in Table 32-12.

Table 32-13 is intended to provide the cytopathologist with a quick reference to the most likely differential diagnosis based on the most prominent cytologic features of the aspirate.

The Prostate and the Testis

THE PROSTATE

The purpose of cytologic or histologic sampling of the prostate is the **diagnosis of prostatic carcinoma**. In the past, the presumptive clinical diagnosis of prostatic cancer was based on finding palpable nodules on rectal examination. In 1930, Ferguson, working at the Memorial Hospital for Cancer in New York where the aspiration of various organs was extensively used, reported that cytologic examination of such nodules was diagnostically helpful and accurate.

Within the recent years, rectal examination is supplemented by testing for **serum level of prostate specific antigen (PSA) which has become the principal means of detection of occult, localized carcinoma of the prostate** (Catalona et al, 1991; Stenman et al, 1999; Brawer, 2000). Elevation of PSA, beyond the levels established for various age groups (4 to 6 µg/liter), is an indication for a **transrectal ultrasound examination** of the prostate that may reveal foci of abnormalities not recognizable by palpation (Cooner et al, 1990). The finding of such abnormal areas in the prostate is usually followed by **either core or fine (thin) needle aspiration (FNA) biopsies** to confirm the presence of prostatic carcinoma prior to treatment.

It should be stressed that **elevation of the levels of PSA** also depends on the **volume of the prostate**: it may be increased in benign prostatic hypertrophy and prostatitis, and may be transient (Lieber et al, 2001). For this reason, refinement of the PSA testing has been proposed within recent years. Thus, the ratio of **free to protein bound PSA** (specifically to α_1 -antichymotrypsin and sometimes other enzymes) is lower in prostatic carcinoma than in benign disease (Stenman et al, 1999). Prostatic carcinoma may also be associated with increased **PSA density and velocity** measured on multiple tests over a 3 year period (Polascik et al, 1999; Kamoi and Babaian, 1999; Nash and Melezinek, 2000). On the other hand, a **small percentage of patients with prostatic carcinoma have normal PSA levels** (Stamey and Kabalin, 1989).

The current aggressive approach to the treatment of

P.1263

prostatic carcinoma by radical surgery or radiotherapy, often combined with chemotherapy, affecting ever younger men, disregards the fact that prostatic carcinoma is one of the **most common forms of occult cancer found at autopsy of elderly men, reaching 80% in men aged 80 or above** (Peterson, 1992). Thus, it is likely that at least some of the treated carcinomas would not be lethal to the patients within their natural life span. In fact, several long-term follow-up studies of patients with untreated, low-grade prostatic carcinoma have shown that they have a minimal risk of dying of the disease (Johansson et al, 1992, 1997; Albertsen, 1998).

Although there are some fairly reliable prognostic factors, discussed below, to assess the

behavior of prostatic carcinomas, they are rarely applied to treatment decisions in individual patients, many of whom believe that all prostate cancers are a rapidly progressing deadly disease. Equally disturbing is the **absence of randomized trials**, documenting that PSA testing does reduce mortality from prostatic carcinoma (Barry, 2001).

Be it as it may, extensive testing for PSA has raised the status of prostatic carcinoma from a relatively unimportant disease several years ago to the forefront of health care of men with 198,000 new cancers and 31,000 deaths from this disease projected by the American Cancer Society for the year 2001 (Greenlee et al, 2001). Men of African origin appear to be at a high risk for this disease which is relatively uncommon among the Japanese. Prostatic carcinoma can occur in families, but its causes and risk factors are generally unknown.

SAMPLING METHODS

Voided Urine

Cells of prostatic cancer may occasionally be observed in voided urine, as described in Chapter 23. The finding is usually incidental and reflects advanced disease.

Prostatic Massage

Prostatic massage is commonly used by urologists to obtain samples of prostatic secretions for rapid microscopic analysis, mainly for identification of leukocytes in cases of prostatitis. This method had been used to secure samples for **diagnosis of prostatic carcinoma** in patients with **palpable prostatic abnormalities** with a measure of success (Frank et al, 1954; Frank, 1955; Bamforth, 1958; Clarke and Bamford, 1960). However, the method is not suitable for detection of **occult prostatic carcinoma**, as was shown in a large study of over 2,000 **asymptomatic patients** aged 50 or older (Riaboff, 1954; Richardson et al, 1954).

Transrectal Aspiration Biopsy

The development of a special instrument for prostatic aspiration (Franzén et al, 1960) led to an effective method of cytologic sampling of the prostate by **transrectal fine (thin) needle aspiration biopsy (FNA)** (Fig. 33-1). The scope, significance, and clinical value of the aspiration biopsy of the prostate has undergone significant changes since the late Dr. Josef Zajicek eloquently and enthusiastically described it in the previous editions of this book. The changes were caused by new developments in **ultrasonographic techniques that are capable of identifying small space-occupying lesions of the prostate** that can be sampled by **core biopsy instruments** that many clinicians find easier to use than the cumbersome aspiration apparatus. Further, pathologists with limited experience in diagnostic cytology find the core biopsies easier to interpret than aspiration cytology. Core biopsies offer the additional advantage of a more **precise localization** of the lesions within the target organ. Still, the FNA of the prostate offers **several advantages**:

Figure 33-1 Apparatus for transcutaneous and transrectal aspiration biopsy: needles of various sizes (*top*), aspiration syringe with a special handle (*center*), needle and needle-guide for transrectal aspiration biopsy (*bottom*), shown at about 50% of original size. Although contemporary syringes and syringe holders are somewhat different, this photograph adequately reflects the basic armamentarium necessary for aspiration biopsy.

- It is an office procedure.
- It is well tolerated by the patients because the discomfort and trauma from the 22-gauge needle are minimal.
- Sampling area is larger than that of core biopsies.
- Smears can be processed and interpreted rapidly.
- It is accurate in experienced hands.
- It is cost effective.
- Complications are very rare and easily preventable.

Disadvantages

The main disadvantage of the aspiration is that it is **limited to palpable lesions**. Another disadvantage is the **complexity of the instrument** requiring considerable **training, experience and clinical skills to perform the**

P.1264

aspiration quickly and effectively (Ljung et al, 2001). In the Montefiore Hospital experience, with 1,683 patients sampled by a group of practicing urologists or urology residents without specific training in the technique of aspiration, **37% of the samples were inadequate** (Koss et al, 1984; Suhrland et al, 1988). Most American urologists have now abandoned the

aspiration procedure in favor of the core tissue biopsy (see below). Still, the aspiration biopsy of the prostate is a **useful and accurate diagnostic procedure**, if the expensive ultrasound or core biopsy instruments are not available.

An additional application of cytologic aspiration techniques to prostatic carcinoma was described by Van Poppel et al (1994). These investigators used computerized tomography-guided **transcutaneous aspirations of pelvic lymph nodes** to identify **metastatic carcinoma** with high sensitivity and specificity.

Aspiration Procedure using Franzén's Instrument

As shown in Figure 33-1, the aspiration of the prostate calls for a specially constructed 22-gauge, 20-cm in length flexible needle, which is slightly thicker and rigid in the proximal 5 cm. The transition from the thicker to the thinner part of the needle serves as a marker (see below). A needle guide, consisting of a fine metal tube curved to fit the palpating finger, is required (see Fig. 33-1, *bottom*). The length of the guide equals that of the thinner part of the needle. To facilitate introduction of the needle into the guide, the latter is enlarged at its proximal end like a funnel. At the distal end of the guide, there is a steering ring for the palpating finger. This may be adjusted to fit the operator's finger. An adjustable plate, midway along the guide, serves to support the instrument by resting on the palm of the gloved nondominant (usually left) hand of the operator. The index finger of the gloved hand is passed through the steering ring, leaving the fingertip free. To fix the guide more firmly on the palpating finger and to avoid contamination, a finger-cot is thereafter pulled over the index finger. The support plate is adjusted to rest on the palm of the hand and kept in place by pressure of the remaining fingers flexed against the palm. The needle is introduced through the funnel into the guide until the thicker part of the needle approaches the funnel. At that moment, the needle point is nearing the end of the guide immediately below the finger-cot (Fig. 33-2).

The aspiration is performed with the patient in lithotomy position. No anesthesia is required, except in patients with inflamed hemorrhoids or anal fistula who receive an anesthetic jelly. Careful digital examination of the lesion to assess its size and consistency is first made. The left index finger, with the instrument arranged as shown in Figure 33-3, is then inserted into the rectum. The finger must be well lubricated and must be inserted slowly and carefully, as this may be the most uncomfortable moment for the patient, particularly if there is an anal spasm.

The suspected area of the prostate is now palpated with the index finger of the nondominant hand, after which **the needle is advanced into the lesion** with the plunger of the syringe down. When the needle has entered the lesion, **several small amplitude to-and-fro movements of the needle** are performed to loosen the target tissue. Negative pressure is obtained by pulling on the syringe plunger in order to aspirate the material onto the needle. **Before withdrawing the needle from the prostate, the negative pressure must be released**, a most important step that will ensure that the **aspirated material remains in the needle** and does not enter the barrel of the syringe, where it is irretrievably lost. If several areas of the prostate require aspiration, the needle has to be withdrawn and replaced with another needle. **It is not advisable to attempt to change the direction of the needle, while lodged in the target tissue, because of risk of a hemorrhage and injury to the prostate.** The smears are prepared from needle contents, as described in Chapter 28, and processed as either air-dried or alcohol-fixed smears. Most patients tolerate the procedure well. Significant **discomfort** was reported by only a few patients with acute prostatitis and prostatic carcinoma. Repeat aspirations were readily accepted by the patients.

Figure 33-2 The instrument for transrectal biopsy, arranged in the operator's left hand.

Although the procedure described above was initially devised by Franzén et al for prostatic aspiration, it is also applicable to the **sampling of the ovary and the parametria** (see Chap. 15).

Figure 33-3 Position of the left hand during transrectal aspiration biopsy. Prostate in sagittal section showing the needle inserted into the suspected, indurated area. (Franzén S, et al. Cytologic diagnosis of prostatic tumors by transrectal aspiration biopsy: A preliminary report. Br J Urol 32:193-196, 1960.)

In the approximately 17,000 transrectal prostatic aspiration biopsies initially performed at the Karolinska Hospital in Stockholm, Sweden between 1956 and 1966, **no major complications** were observed. Minor complications, such as transient hematuria, acute epididymitis, hematospermia or transient pyrexia, occurred in 0.4% of patients.

In the subsequent years, however, when the number of needle biopsies increased sharply, there were **four cases of severe, gram-negative septicemia, one with a fatal outcome** (Esposti et al, 1975). It was noted that the **febrile reactions were more common in patients with prostatitis, reaching 6.3% of patients in some groups**. The obvious conclusion was that transrectal aspiration biopsy should **not be undertaken in patients with current prostatitis**. It is still a matter of debate whether prophylactic treatment with antibiotics is effective in preventing septicemia. Because of the remote possibility of septicemia, every patient undergoing a transrectal aspiration biopsy of the prostate should be advised to contact his own physician or the nearest hospital should a febrile reaction occur. However, a **past history of prostatitis does not, in itself, contraindicate an aspiration biopsy because 10% in this group of patients were found in the Swedish study to have carcinoma**.

Core Biopsies

Today, most urologists prefer **multiple core biopsies** performed with a semi-automated instrument **under ultrasound guidance** for diagnosis of prostatic carcinoma. The method requires no anesthesia and is usually performed transrectally as an outpatient procedure. Tissue biopsies, obtained from six to twelve areas of the prostate are, not only diagnostic, but are also predictive of stage and grade of carcinoma (Wills et al, 1998). The accuracy of this procedure in the diagnosis of prostatic carcinoma is similar to that of expertly performed aspiration biopsies (see below for comparison of results of the two procedures). The **complications** of core biopsies are similar to those observed with the FNA procedure and include **gram-negative septicemia** that may be fatal.

Figure 33-4 A. Diagrammatic sagittal section through the bladder, prostate, and seminal vesicles. B. Normal prostate, showing the glands and the fibromuscular stroma. Prostatic secretions are seen in one gland. C. Seminal vesicle. Complex tubular structures with granules of yellow lipochrome pigment in the cytoplasm of the glandular cells lining the tubules. Large, hyperchromatic nuclei may be noted in some of the cells.

ANATOMY AND HISTOLOGY OF THE PROSTATE AND SEMINAL VESICLES

The prostate is a complex gland encased in a pseudocapsule of fibromuscular tissue (Fig. 33-4A). The **prostatic glands, or acini, and ducts are lined by cuboidal to columnar epithelium with small, spherical nuclei. Nucleoli are absent, or very small, and barely visible under the high power of the microscope** (Fig. 33-4B). The normal prostatic glands are provided with layers of **basal epithelial cells** that can be demonstrated by immunostaining with antibodies to **high molecular weight keratins** (keratin 903). This layer is **usually absent in prostatic carcinoma**, a feature that is sometimes helpful in differentiating atypical benign

P.1266

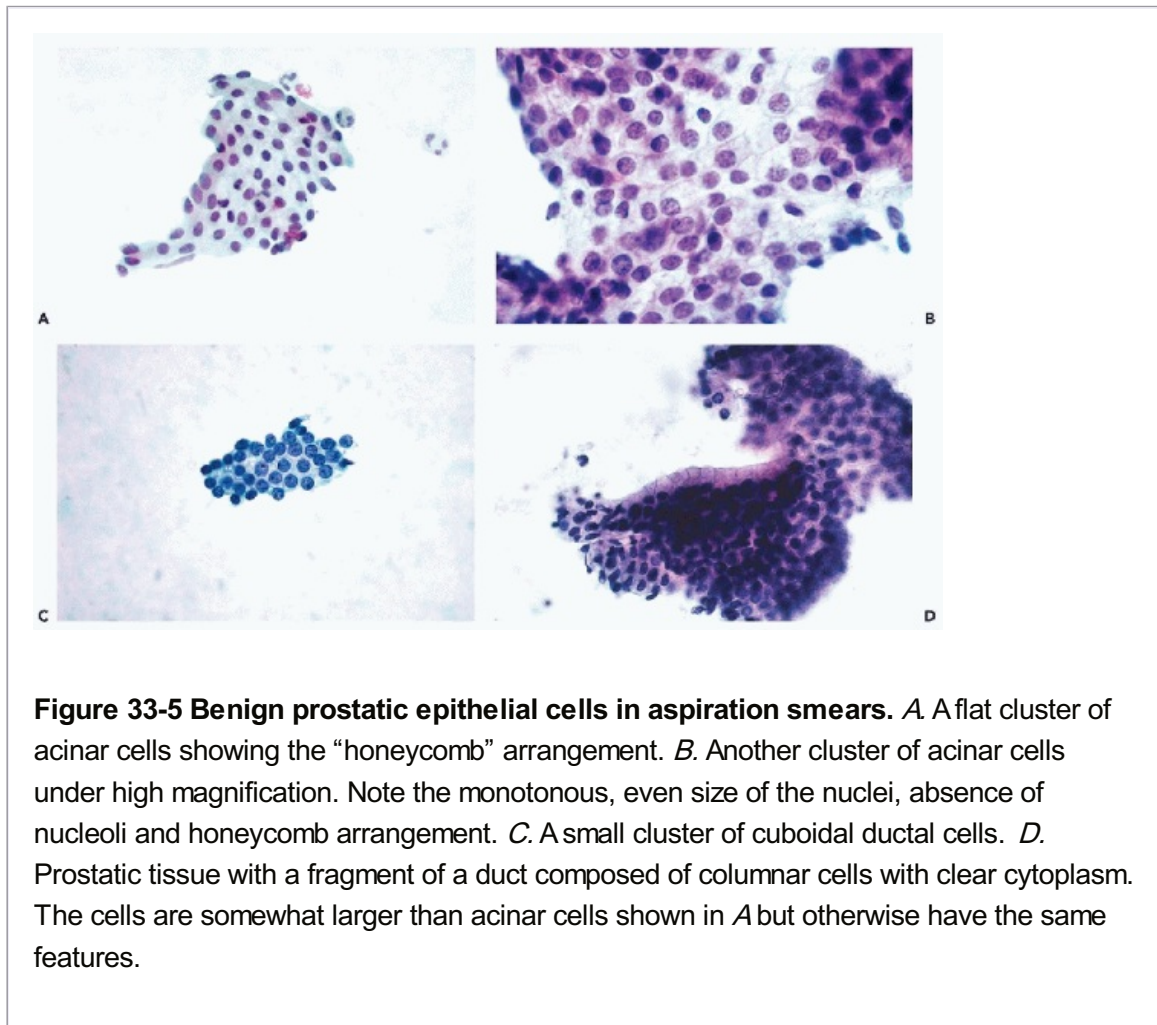

prostatic epithelium from well differentiated adenocarcinoma (Hedrick and Epstein, 1989; Shah et al, 1991).

It is a matter for some debate whether the prostatic glands are surrounded by **myoepithelial cells** which are extremely difficult to visualize in histologic sections. However, there is no doubt that **small, spindly, dark cells**, recognized in other organs as myoepithelial cells, can be seen in prostatic aspiration smears.

Within the lumina of the glands, one may frequently observe **concretions of prostatic secretions (corpora amylacea)** that may undergo calcification and thereby form “**prostatic**

calculi” (Fig. 33-4B).

The sexual apparatus of men also includes two symmetric glandular structures—the **seminal vesicles, attached to the posterior aspect of the prostate** (see Fig. 33-4C). The seminal vesicles are in close relationship with the spermatic ducts, with which they share a common opening in the prostatic urethra. The **seminal vesicles are lined by columnar cells, characterized by accumulation of a yellow lipochrome pigment in the cytoplasm**. These cells are also notable **for marked variability in nuclear sizes; in some cells, the nuclei are markedly enlarged and hyperchromatic** (Arias-Stella and Takano-Moron, 1958). **Spermatozoa and their precursors** are stored within the lumens of the seminal vesicles.

CYTOLOGY OF NORMAL PROSTATE

Aspiration Biopsy

The microscopy of prostatic smears should begin at **low magnification**. In benign conditions, there is usually a thin film of blood and fluid with a small number of **sheets of epithelial cells**. If the aspirate has been properly spread on the slide, most of the prostatic cell clusters will be found at the end of the slide. **An adequate smear will contain at least 10 to 12 clusters of epithelial cells.**

Prostatic Epithelial Cells

Normal prostatic epithelial **acinar cells** form **flat sheets of uniform small cells with clear cytoplasm and small, spherical nuclei of even sizes**. The cytoplasmic borders are readily

seen as thin lines separating the cells from each other (**honeycomb effect**) (Fig. 33-5A,B). These cells are seen only in direct aspirates of the prostate. Comma-shaped, dark nuclei, resembling **myoepithelial cells**, may be sometimes

P.1267

observed at the periphery of such clusters under high power. **The ductal cells** are somewhat larger and are usually of **cuboidal or columnar** shape (see Fig. 33-4C). In fortuitous cases, the ducts appear as a row of columnar cells lining a fragment of prostatic tissue (see Fig. 33-4D). These cells may also occur singly, but usually form **flat, "honeycomb" - type clusters** with one flat surface, corresponding to the lumen of the duct. **These cells have small, spherical nuclei**, similar to those of acinar cells, and may contain small chromocenters (see Fig. 33-5C). The cytoplasm of these cells is finely granular, or clear, and contains demonstrable acid phosphatase and prostate-specific antigen. In May-Grünwald-Giemsa or Diff-Quik-stained smears (Diff-Quik, Dade Behring Inc., Deerfield, IL), bluish to purple colored, **cytoplasmic granules** of variable size can be seen in the cytoplasm. Opaque, homogeneous **prostatic concretions (corpora amylacea)**, that are sometimes **calcified**, are not uncommonly seen (see Fig. 33-6D).

Other Cells

Benign cells, not of prostatic origin, that may be observed in the urinary sediment and in **prostatic aspirates** and may be of diagnostic significance, are the **seminal vesicle cells**, **urothelial cells**, **colonic epithelium**, **squamous cells** and **bone marrow and ganglion cells**.

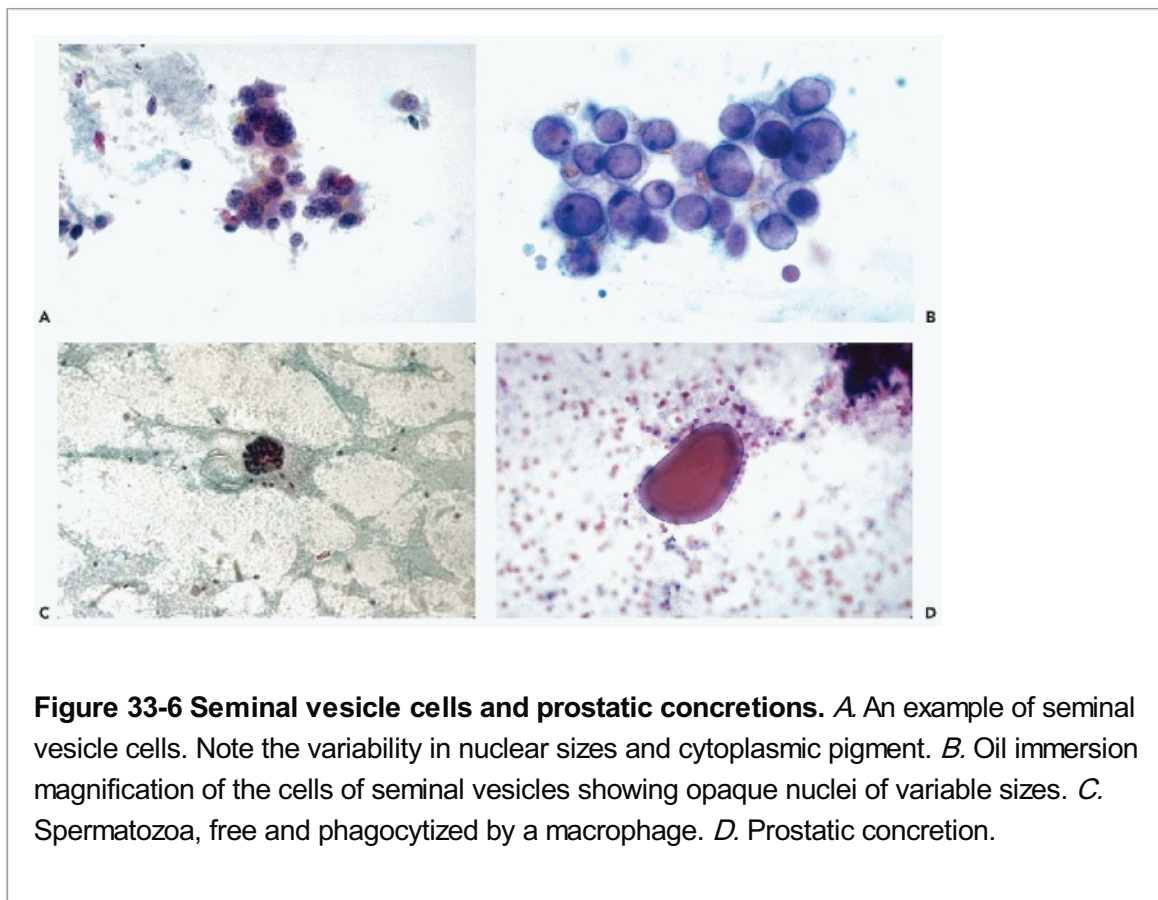

Figure 33-6 Seminal vesicle cells and prostatic concretions. *A.* An example of seminal vesicle cells. Note the variability in nuclear sizes and cytoplasmic pigment. *B.* Oil immersion magnification of the cells of seminal vesicles showing opaque nuclei of variable sizes. *C.* Spermatozoa, free and phagocytized by a macrophage. *D.* Prostatic concretion.

Seminal vesicle cells are often characterized by **very large, opaque, homogeneous, dark nuclei** and **granular deposits of cytoplasmic brown or yellow lipochrome pigment** (Fig.

33-6A,B). Cells of the seminal vesicles are more often observed in **prostatic aspirates** than in urinary sediment, where they may be seen after prostatic massage. These cells may also occur in cervicovaginal smears after intercourse (see Chaps. 8 and 10). Because of their nuclear features, these cells may be **readily mistaken for cancer cells** (Droese and Voeth, 1976; Koss et al, 1992). The cells may be correctly identified because of the presence of **cytoplasmic pigment**. Another common identifying feature of these cells is the company of spermatozoa and their precursors. In aspirates, the seminal vesicle cells are often accompanied by circular eosinophilic droplets of accumulated secretions that are much smaller than the corpora amylacea.

Spermatozoa are readily recognized by their small size, small oval nuclei and the presence of long tails. They may be numerous in specimens obtained by prostatic massage and in aspirates that inadvertently penetrated the lumen of the seminal vesicles. On occasion, **macrophages containing numerous phagocytized spermatozoa may be noted** (Fig. 33-6C). Characteristically, the tails of the spermatozoa often remain outside the macrophage. The precursor cells of spermatozoa or **spermatogonia** appear as small cells, about the

P.1268

size of lymphocytes or slightly larger, with a fair amount of somewhat elongated cytoplasm, and peripheral, relatively large, dark nuclei. These cells are illustrated below, in reference to the testis.

Urothelial cells are common in urine sediment and may occur in aspirates wherein the needle is too deeply inserted and reaches the **trigone of the bladder**. Such cells are readily recognized, particularly when the **superficial umbrella cells** are present in the smear (Fig. 33-7A). For a detailed discussion of the morphology of these cells, see Chapter 22.

Colonic epithelial cells are seen in aspirates if the needle is withdrawn to the level of the colonic mucosa, before releasing the piston of the syringe to equalize the vacuum. **Clusters of large, columnar goblet cells, with clear, mucus-containing cytoplasm and peripheral nuclei** are usually readily identified (Fig. 33-7B).

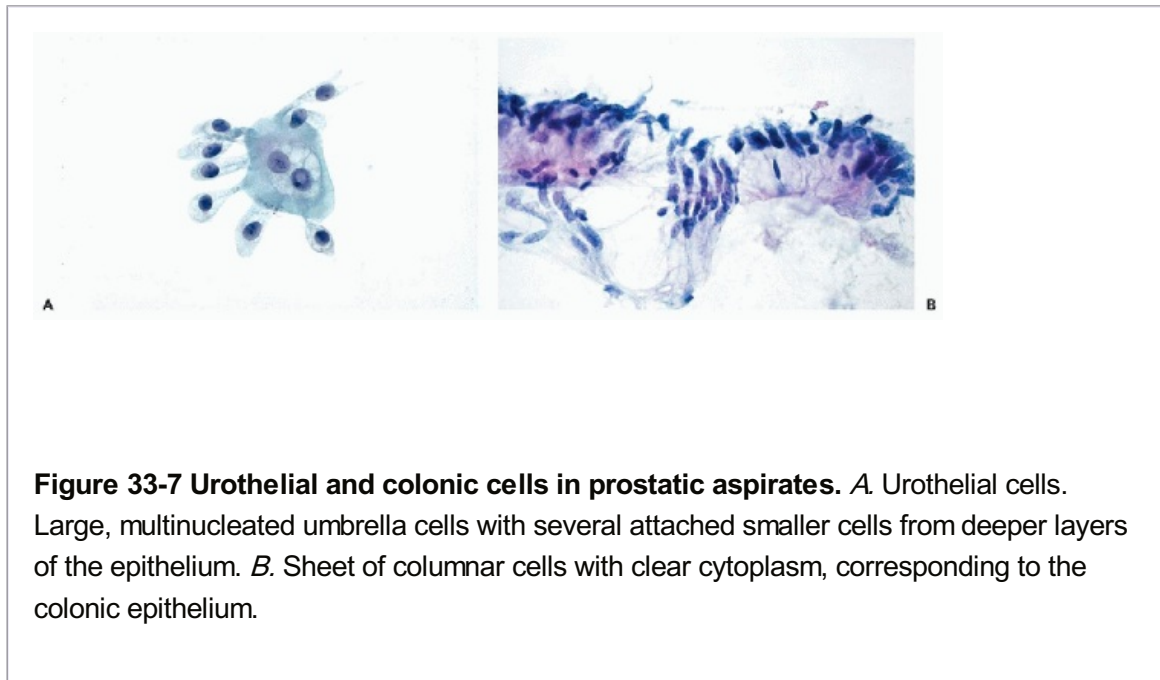

Squamous cells may originate from the **membranous urethra** or from **prostatic infarcts** that may undergo squamous metaplasia. In the latter case, the squamous cells may be of the parabasal variety and show some **nuclear atypia in the form of small nucleoli** (Koss et al, 1992). Squamous cells may also be observed in patients **treated for prostatic carcinoma** (see below).

Bone marrow cells, notably **large polynucleated megakaryocytes** and **large ganglion cells with prominent nucleoli** accompanied by nerve fibers, may be observed if the inexperienced operator aspirates, respectively, the bone marrow or the anterior surface of the sacrum (Greenebaum, 1988). The **large ganglion cells** may be readily **mistaken for cancer cells** by an unfamiliar observer (see Chap. 16).

Urine Sediment and Prostatic Fluid

Cells of normal prostate and seminal vesicles are uncommon in spontaneously voided urine, except after intercourse or after prostatic massage. After prostatic massage, the sediment may contain cells of prostatitic ducts, seminal vesicles, bladder and urethra, and the sperm, or its predecessors. In the absence of disease, acinar prostatic cells are practically never seen in the urinary sediment. Occasionally, **a few round squamous cells containing yellow deposits of glycogen may be noted**. These cells are more commonly seen as a result of therapy (see below) but they may also be present in the absence of treatment. Small,

concentric, yellow or purple, but occasionally calcified, **prostatic concretions** (corpora amylacea), are easily recognized (see Fig. 33-6D). **Spermatozoa, and their precursors**, may be observed after prostatic massage or after intercourse (see Fig. 33-6C). Nearly every prostatic massage specimen will contain a few cells very difficult to classify accurately because of the complexity of the participating epithelia.

CYTOLOGY OF PROSTATIC ASPIRATION SMEARS IN BENIGN DISORDERS

Although the primary target of aspiration biopsy is **prostatic carcinoma**, a number of benign **lesions** may **mimic prostatic carcinoma** on clinical examination or on ultrasound and may be inadvertently sampled. These are:

- **Benign prostatic hypertrophy**
- **Chronic prostatitis**
- **Granulomatous prostatitis**
- **Prostatic infarcts and other rare benign disorders**

Benign Prostatic Hypertrophy

Benign prostatic hypertrophy or hyperplasia consists of an enlargement of the prostate caused by increase in the number of glands, increase in the amount of stroma, or both. It is a very common disorder in elderly men. It is not clear whether prostatic hyperplasia is a precursor lesion of prostatic carcinoma (Greenwald et al, 1974). Still, in some patients treated for hyperplasia by suprapubic prostatectomy, foci of occult carcinoma may be discovered (Bauer et al, 1960).

In aspiration smears of benign prostatic hyperplasia,

P.1269

there are large clusters of **essentially normal, flat, nonstratified sheets of benign epithelial cells with striking regularity of architecture** (see Fig. 33-5B,C). The relatively few dissociated cells have the same appearance as the clustered cells. Another type of cell grouping in benign prostatic hyperplasia is a large **multilayered plug of ductal epithelial**

cells of quasi-papillary appearance (Fig. 34-8). This may arouse the suspicion of cancer but higher magnification shows that the flat center of the cluster shows “honeycomb” arrangement of epithelial cells with **spherical nuclei of even sizes and barely visible or absent nucleoli**.

Prostatitis

Bacterial or Viral Prostatitis

As mentioned above, patients with evidence of prostatitis are at risk of septicemia and **should not be aspirated**. Still, occasionally, aspiration smears are obtained and show variable numbers of **inflammatory cells**. In acute inflammation, neutrophil granulocytes predominate. In less acute forms, the smears show monocytes, lymphocytes and macrophages, next to neutrophil granulocytes. **Macrophages** may be numerous. The **prostatic glandular cells often show degenerative changes**, such as **vacuolization of the cytoplasm, swelling or pyknosis** and **break-up of the nuclei (karyorrhexis or apoptosis)**. Some **variations in the nuclear size and shape** and the **presence of small nucleoli** may occur. In the presence of nucleoli, it is difficult to exclude the possibility of cancer or a precancerous lesion. However, evidence of inflammation is very uncommon in smears of prostatic carcinoma and should serve as a deterrent to a false positive diagnosis. In debatable cases, we usually recommend repeat aspiration or tissue core biopsy after treatment of the inflammation.

Granulomatous Prostatitis

Granulomatous inflammation of the prostate may be a **primary event** or a **secondary** complication of a generalized granulomatous inflammation occurring in **tuberculosis, sarcoidosis or fungal infection**. We have not seen patients with granulomatous prostatitis caused by infectious agents or sarcoidosis. However, several published reports indicate that **granulomas, composed of epithelioid and giant cells and caseous necrosis**, may be observed in **tuberculous prostatitis** (Miralles et al, 1990; Garcia-Solano et al, 1998). Prostatic granulomas may also occur during and after **treatment of bladder cancer with bacillus Calmette-Guérin (BCG)** (see Chap. 23). Although epithelial cell atypia may be observed in such cases, the comments pertaining to prostatitis are valid here as well, to wit, that **prostatic cancer cells are rarely accompanied by inflammatory events** but, in doubtful cases, tissue biopsy may be indicated.

Figure 33-8 Benign prostatic hypertrophy. A. A very large sheet of prostatic epithelial cells with ductal cells forming the flat center of the cluster and several peripheral cell

clusters derived from adjacent, smaller ducts. *B.* Corresponding tissue section.

A relatively rare, but distinct, type of inflammatory process is **granulomatous eosinophilic prostatitis**, which is observed in patients with allergic conditions such as bronchial asthma. Despite its comparative rarity, granulomatous eosinophilic prostatitis is clinically important, since it causes **induration and partial fixation of the gland** and, thus, may strongly suggest prostatic carcinoma on digital examination. In the prostate, granulomas with a necrotic center and a palisading of epithelioid cells at the periphery may be observed. Numerous eosinophiles are seen in the background. In **aspiration biopsy smears**, the inflammatory cell population is dominated by **plasma cells and eosinophilic leukocytes. Comma-shaped epithelioid cells and multinucleated giant cells may be observed** (Fig. 33-9).

Parasites

Gardner et al (1986) observed the presence of *Trichomonas vaginalis* in otherwise normal prostates. For description of the parasite, see Chapter 10. In tropical countries, other parasites, such as *filaria species*, may be observed.

Prostatic Infarcts

These are uncommon events, occurring in **benign prostatic hyperplasia**, wherein a **sharply demarcated area of the prostate becomes necrotic**. Although the term "infarct" is used to describe such events, evidence of vascular occlusion

P.1270

is often lacking. Infarcts may undergo **squamous metaplasia**. **The squamous epithelium, that may be mature or immature**, is presumably derived from adjacent prostatic epithelium. Infarcts of the prostate may be **mistaken for cancer on ultrasound examination** and the lesions may be aspirated.

Figure 33-9 Multinucleated macrophage from an aspirate in a case of granulomatous prostatitis.

In our very limited experience, the aspiration smears may contain **necrotic tissue** and scattered **mature and immature squamous cells that may be mistaken for cells of the extremely rare squamous carcinoma of the prostate** (Koss et al, 1992).

PROSTATIC CARCINOMA

Histology

Most prostatic **adenocarcinomas** originate in the glands or acini of the posterior lobe of the prostate. It is estimated that about 25% of these tumors originate in the anterior lobes (for review of this topic, see Koss, 1995). A more elaborate analysis of the origin of these tumors is irrelevant in the context of this book. The tumors are composed of abnormal prostatic glands which, at one end of the spectrum, may show only minimal nuclear abnormalities (enlarged nucleoli) and, at the other end of the spectrum, are composed of obvious cancer cells.

Grading of prostatic carcinoma has been shown to be of prognostic value (Mostofi, 1975). Grading may be based on the level of cytologic abnormality, but a classification system based on histologic patterns, proposed by Gleason et al (1979), is now widely used. The **Gleason system** puts a numerical value on the **primary or dominant and secondary histologic patterns**, ranging from 1 to 5. Thus, the tumors may be very **well differentiated** and mimic closely the make-up of normal prostatic glands, except for invasion of stroma (low-grade carcinomas, Gleason 1 + 1 = 2 or 2 + 1 = 3 or 2 + 2 = 4); **moderately differentiated**, with significant abnormalities of the glands and the component cells, but retention of the glandular pattern (Gleason 3 + 3 = 6 or 3 + 4 = 7); or **poorly differentiated**, with loss of glandular pattern and marked cytologic abnormalities (Gleason 4 + 5 = 9 or 5 + 5 = 10). The moderately and poorly differentiated tumors tend to **invade the capsule of the prostate, periprostatic nerves and metastasize to regional lymph nodes and bone**.

It is thought that prostatic carcinomas are preceded by precancerous abnormalities known as **prostatic intraepithelial neoplasia (PIN)** (Bostwick et al, 2000). To our knowledge, aspiration cytology is not useful in the recognition of this condition, although there may be rare exceptions to this statement (DeGaetani and Treutini, 1978).

Prostatic cancer may show a dependency on hormones. **Estrogens**, or their chemical substitutes or, more recently, **androgen agonists**, may temporarily arrest the spread of prostatic cancer and bring about subjective and objective improvement.

Tumor **staging reflects the relationship of the tumor with adjacent structures**. Tumors still confined to the prostate are stage A or I, whereas tumors forming metastases are stage D or IV. Most of the low-stage, low-grade tumors are discovered in asymptomatic patients investigated because of a rise in PSA levels. Tumors discovered by palpation are usually of higher grade and stage.

Carcinomas, primary in the prostatic ducts, are distinctly uncommon (Dube et al, 1973; Christensen et al, 1991; Vandersteen et al, 1997). They have a great deal of histologic **similarity to ductal carcinomas of the breast**. They must always be **differentiated from urothelial carcinoma (including carcinoma in situ) of bladder that may extend into prostatic ducts** (see below and Chap. 23). **In the presence of a solid carcinoma in prostatic ducts, a search for a carcinoma in situ of the bladder is mandatory** (Barlebo and Sørensen, 1972). There appears to be considerable confusion among pathologists who consider **adenocarcinomas of the prostatic utricle**, resembling endometrial cancer

described in Chapter 23, as equivalent of ductal carcinoma of the prostate (Brinker et al, 1999). We believe that these are two distinct tumors, one resembling endometrial carcinoma and the other mammary carcinoma.

Another uncommon type of prostatic carcinoma is the **small cell carcinoma** that may be either primary or a component of a conventional adenocarcinoma (Tetu et al, 1987). Other **very rare types of prostatic carcinoma, including endocrine carcinomas**, were discussed by Peterson (1992) but have a very limited bearing on the interpretation of the aspiration biopsy.

Van de Voorde et al (1994) described a **mucin-secreting adenocarcinoma** of the prostate with marked endocrine differentiation. This is in contrast to **focal presence of neuroendocrine cells that is common in prostatic cancer** and has no documented clinical significance (di Sant'Agnese, 1992).

Cytology

Voided Urine and Prostatic Massage

Cells of prostatic carcinoma may be observed in **voided urine, usually in advanced prostatic cancer. The cancer**

P.1271

cells are usually small and either occur singly or form loosely structured clusters (Fig. 33-10). **The nuclei are relatively large and hyperchromatic and often contain clearly visible nucleoli.** Morphologic recognition of tumor origin and type is difficult in the absence of clinical data.

Figure 33-10 Prostatic carcinoma in voided urine. A small cluster of small cancer cells with relatively large, hyperchromatic nuclei. The details of the nuclear structure are not visible. The prostatic origin of the cluster is not secure.

In specimens obtained by **prostatic massage**, the material obtained is rarely optimal and does not compare favorably with smears obtained by prostatic aspiration, discussed below. The appearance of cancer cells varies according to the degree of histologic differentiation of the

tumor and is similar to that described below for aspiration biopsies, except that cancer cells are usually few in number and fine points of nuclear structure are rarely evident. In the 1950s and 1960s, prostatic massage technique was used to recognize occult prostatic carcinoma with rather poor results (Frank, 1955; Frank et al, 1958; Riaboff, 1954; Richardson, 1954). The cytologic findings in the rare, poorly differentiated carcinomas involving simultaneously the bladder and the prostate (**uroprostatic carcinoma**) were discussed in Chapter 23.

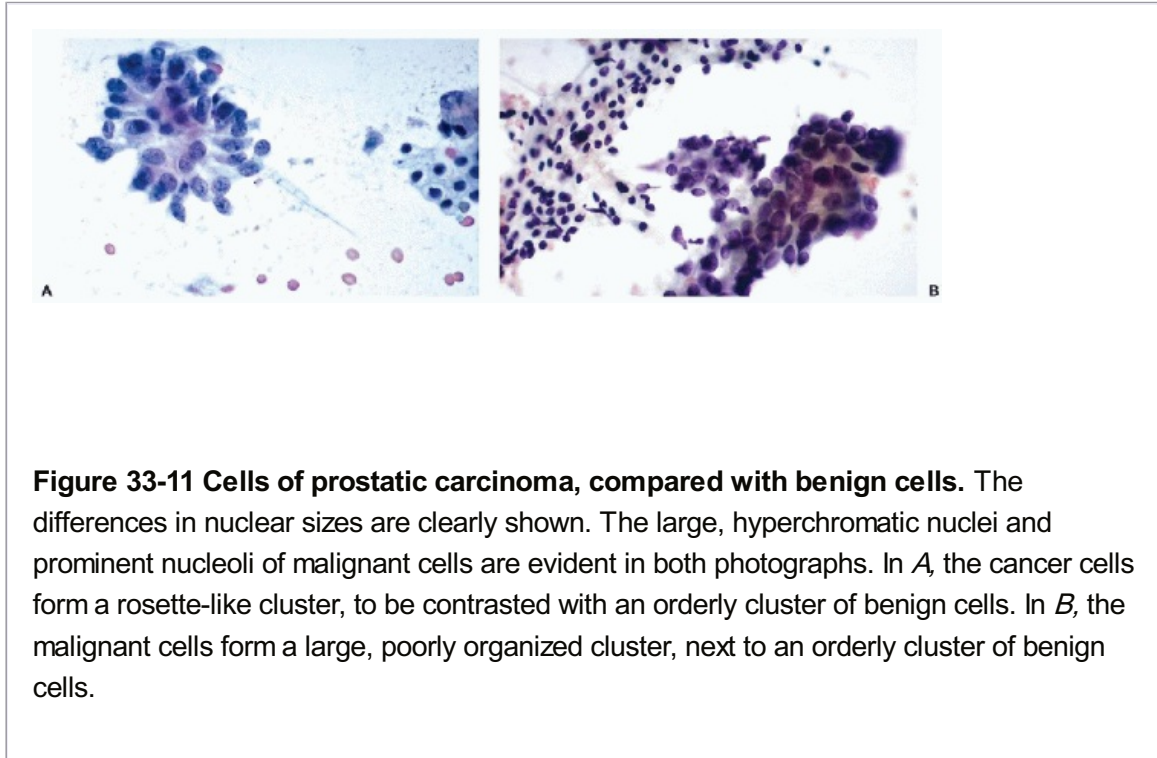

Figure 33-11 Cells of prostatic carcinoma, compared with benign cells. The differences in nuclear sizes are clearly shown. The large, hyperchromatic nuclei and prominent nucleoli of malignant cells are evident in both photographs. In *A*, the cancer cells form a rosette-like cluster, to be contrasted with an orderly cluster of benign cells. In *B*, the malignant cells form a large, poorly organized cluster, next to an orderly cluster of benign cells.

Aspiration Cytology

The adequate aspiration smears in prostatic adenocarcinoma are usually **richer in cells than smears from benign conditions**. Often, there is no admixture of blood, which gives a distinctive appearance to the dried, unstained smears. **Inflammatory cells are rarely present** and the smear usually shows only benign and malignant epithelial cells, occurring singly and in clusters.

When the benign and malignant cells are present side-by-side in the same smear, the differences in cell and nuclear configuration sizes become instantly evident (Fig. 33-11). As previously described, the benign cells form orderly arrays of cells with small, even nuclei. The larger size of the malignant cells and their large, hyperchromatic nuclei with prominent nucleoli are evident. In Figure 33-11A, the malignant cells form a **rosette-like** structure, whereas in Figure 33-11B, the cancer cells form a **3-dimensional, loosely structured cluster surrounding central empty, spherical spaces**. Both configurations of malignant cells are consistent with adenocarcinoma. Certain differences in configuration of cancer cells according to degree of differentiation can be observed.

In smears from **well-differentiated, low-grade cancers**, the most characteristic feature is the **microadenomatous complex, a structure in which the cytoplasm of the cancer cells is crowded into a central mass, while the enlarged nuclei are arranged at the periphery**. When this pattern is repeated throughout the smear, even without noteworthy nuclear polymorphism, the cytologic picture can be regarded as pathognomonic of well-differentiated prostatic adenocarcinoma (Fig. 33-12). DeGaetani and Treutini (1978) described a patient with

“atypical hyperplasia” of the prostate with positive smears. So far as one can tell, this may be an example of **prostatic intraepithelial neoplasia** observed in smears.

In **moderately well-differentiated adenocarcinoma**, this pattern may still be evident but the component cells are much larger. However, the smears are mainly composed of **more solid groups of malignant cells with pronounced**

P.1272

nuclear polymorphism and **large, irregularly shaped nuclei and prominent nucleoli** (Fig. 33-13).

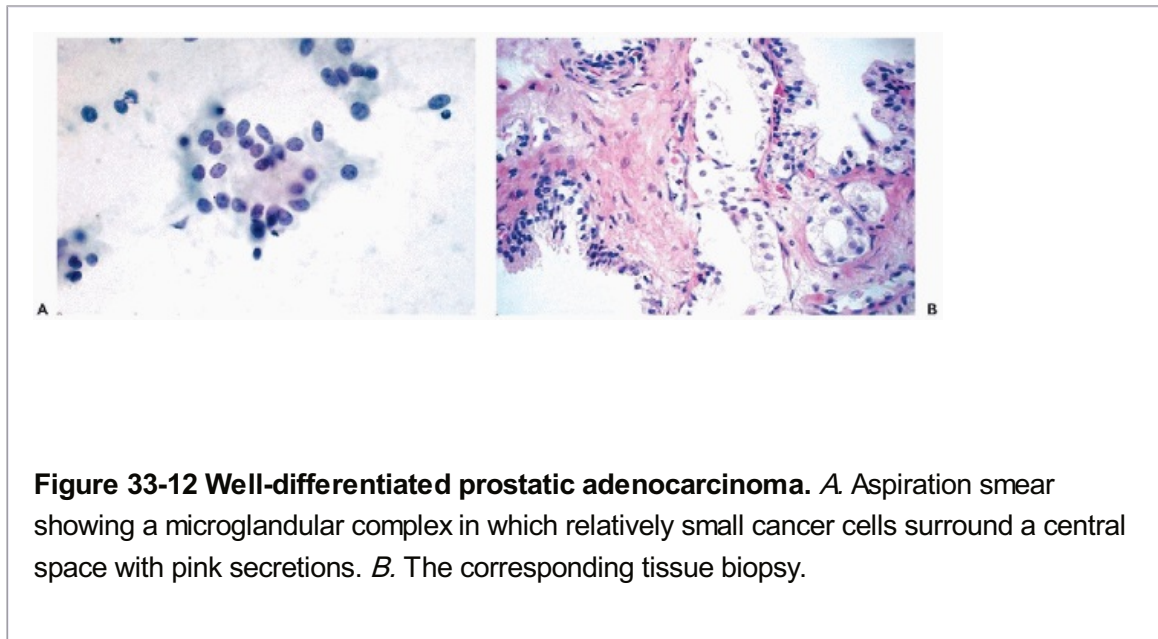

Figure 33-12 Well-differentiated prostatic adenocarcinoma. *A.* Aspiration smear showing a microglandular complex in which relatively small cancer cells surround a central space with pink secretions. *B.* The corresponding tissue biopsy.

In smears from **poorly differentiated prostatic cancers**, the malignant cells are often **dissociated** and may be strikingly **polymorphic** with bizarre forms and very large nuclei (Fig. 33-14). In the **anaplastic variant**, the picture is monotonous and may resemble the pattern of leukemia or lymphoma. Clustering and microadenomatous complexes are rare.

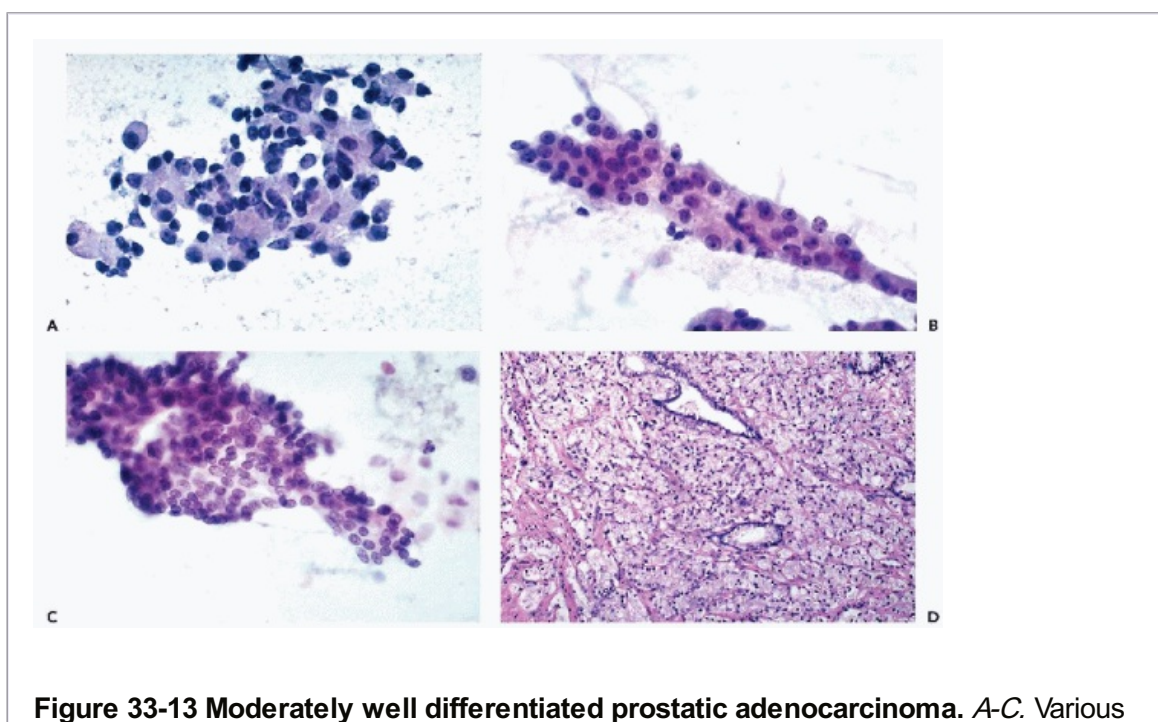

Figure 33-13 Moderately well differentiated prostatic adenocarcinoma. *A-C.* Various

aspects of aspiration smear. *A*. Microglandular complexes formed by much larger cancer cells than in low grade carcinoma (compare with Fig. 33-12A). *B, C*. Solid sheets of cancer cells. *D*. Prostatic biopsy corresponding to *C*.

By far, the most important point in the differential diagnosis of poorly differentiated prostatic carcinoma is urothelial carcinoma of bladder extending to prostatic ducts (Fig. 33-15). The documentation of the source of such tumors may be difficult and may require multiple biopsies of

P.1273

the bladder. In aspiration smears, the urothelial cancer cells are often elongated, have a sharply outlined cytoplasm and hyperchromatic nuclei (see also Chap. 23).

Figure 33-14 Poorly differentiated prostatic carcinoma. The aspiration smear (*A*) shows dissociated highly abnormal, dispersed cancer cells. *B*. The corresponding tissue (prostatectomy).

Cytologic Grade, DNA Ploidy, and Behavior of Prostatic Cancer

On review of the prostatic aspiration biopsies performed at Radiumhemmet in Stockholm during the years 1956 to 1964, the carcinomas were classified as well-differentiated, moderately differentiated, or poorly differentiated tumors, based on cytologic features described above (Eposti et al, 1966). In 206 patients with estrogen-treated carcinomas, a correlation of **cytologic grading** was shown to be of prognostic value. The 3-year survival rate was 80% in the well-differentiated carcinoma, about 60% in moderately differentiated tumors, but only 20% in poorly differentiated cancer. The same survival pattern was observed in the 84 patients followed for 5 years (Fig. 33-16A). Helpap (1981) also concluded that aspiration cytology of the prostate is a reliable medium of tumor grading. Layfield et al (1988) observed that cytologic grading in prostatic aspirates corresponds to Gleason's grading in about 80% of cases. Further, **DNA measurements** by flow cytometry and image analysis systems, have largely confirmed these observations.

Figure 33-15 Urothelial carcinoma in situ in prostatic FNA. *A* A cluster of elongated cancer cells with sharply outlined cytoplasm and large, hyperchromatic nuclei. *B*. Urothelial carcinoma in situ in the trigone of the bladder.

The behavior and prognosis of prostatic carcinoma is reflected in the DNA ploidy of these tumors: diploid tumors are usually of low stage and grade and progress slowly, whereas aneuploid tumors are of high grade and may show rapid progression (Fig. 33-16B) (Bichel et al, 1977; Zetterberg, 1976; Auer and Zetterberg, 1984; Amberson and Koss, 1988). In a consensus statement on prognostic factors in prostatic carcinoma (Bostwick et al, 2000), Gleason's grade was considered to be of prognostic significance but DNA ploidy measurements were not given the same value. This consensus statement is obviously not consistent with our observations or those of other investigators experienced with DNA ploidy measurements which, in our judgment, are **much more reliable than Gleason's grading** and are an **important independent prognostic parameter**.

It has been repeatedly documented, in long-term follow-up studies, that the long-term survival of patients with low-grade, early stage prostatic carcinomas, either not treated or treated with hormone therapy, is excellent and either equal or better than for patients with radical prostatectomy (Johansson et al, 1992, 1997; Albertsen et al, 1998). It is

P.1274

quite likely that the long-term survivors had tumors in the diploid range.

Figure 33-16 Prognostic factors in prostatic cancer. *A.* Cytologic grading of prostatic carcinoma and survival of 206 patients treated with estrogens (January 1956 to June 1963). *B.* Frequency histograms of DNA ploidy in prostatic carcinomas with low (patient group 1) degrees of clinical malignancy. The ploidy abnormality is expressed in percentage of hyperploid cells, defined as cells with DNA values exceeding the upper limit (2.5 c units) of the diploid staining control. The shadowed bars represent patients with combined diploid and tetraploid or pure tetraploid tumors. (Courtesy of Dr. Gert Auer, Stockholm, Sweden.)

Performance of Aspiration Biopsy in the Diagnosis of Prostatic Carcinoma

Initial reports on aspiration biopsy diagnosis of prostatic carcinoma were encouraging but based on a relatively small number of patients (Ferguson, 1930; Clarke and Bamford, 1960). A large scale experience with prostatic aspiration biopsy was reported from the Cancer Center (Radiumhemmet) in Stockholm for the years 1956 to 1964, where 3,002 transrectal aspiration biopsies on 2,410 patients were performed as an outpatient office procedure (Eposti et al, 1966). To ascertain the **diagnostic reliability** of the aspiration biopsy method in prostatic carcinoma, the cytologic results were compared with histologic findings in 162 cases (Eposti, 1966). Cancer was diagnosed from the initial aspiration biopsy smears in 90% of the cases and there were no false positive diagnoses. By repeating the aspiration biopsy after a negative cytologic report, the diagnostic accuracy rose to 95%. In 1974, Eposti updated his results on a still larger group of patients with overall accuracy of 96% and 93% specificity for benign lesions and 97% for cancer. Epstein (1976B) estimated the accuracy at 86%. Similar results were reported by Kline et al (1982), Ljung et al (1986), Klotz et al (1989), and Brenner et al (1990). In our own experience with 214 adequate samples diagnosed as either "positive" or "suspicious," all but two patients with cytologic diagnosis of carcinoma had histologically confirmed prostatic cancer. In the two patients, the follow-up was inadequate. In four of the "suspicious" smears, the diagnosis could not be confirmed and may represent errors of interpretation in prostatitis (Suhrlund et al, 1988).

Comparison of Results of Needle Aspiration Biopsy (FNA) with Ultrasound-Guided Core Biopsies

Al-Abadi (1997) compared the results of the two procedures in 246 patients, 142 with benign lesions, 103 with prostatic carcinoma and 3 with "atypical prostatic hyperplasia." The FNA procedure gave a **sensitivity of 98%**, whereas the ultrasound-guided core biopsies had a **sensitivity of 96%**. Two of the FNA results were false negative, compared with seven initial core biopsies. In these seven cases, the diagnosis of cancer was established on repeat biopsies. In the three cases of "**atypical hyperplasia**," the aspirates were positive. In the absence of illustrations, the nature of these three lesions is not clear. Similar observations have been reported

P.1275

by Couture et al (1980), Klotz et al (1989), and Brenner et al (1990).

Figure 33-17 Effects of estrogen treatment on prostate cancer. *A.* Aspiration biopsy. A single cluster of cancer cells (*center*) is surrounded by squamous cells with rich deposits of glycogen, often pushing the nucleus to the periphery (glycogenic or navicular cells). *B.* Biopsy of prostate showing extensive squamous metaplasia of the cancerous glands.

Al Abadi (1997) reviewed the pertinent literature, notably papers by Bruins et al (1989) and his own previous publication from 1993, and concluded that the **FNA was more accurate, less tedious to the patient, and much cheaper than the core biopsy**. To be sure, expertise in obtaining prostatic aspirates and their interpretation are two key elements in the success of FNA.

Cytologic Effect of Treatment of Prostatic Carcinoma

Application of **estrogens or pharmacologically related compounds** in the treatment of prostatic cancer may result in the presence of **intermediate squamous cells** in voided urine. In Papanicolaou stain, many of these cells contain yellow deposits of glycogen in their cytoplasm (glycogenic or navicular cells) (Fig. 33-17A). These cells originate in the glands of the cancerous prostate which undergo squamous metaplasia under the impact of estrogens (Fig. 33-17B). This type of treatment can also be monitored by **prostatic aspirates**.

A favorable effect of estrogen is also reflected in numerical reduction and degenerative changes in the cancer cells, which finally disappear from the aspirate. Such changes may be observed in aspiration biopsy smears within a few weeks after the start of treatment (Esposti, 1971).

Very little is known about the cytologic effects of newer drugs (**testosterone agonists or androgen blocking agents**) on prostatic cytology. Histologic studies indicate that atrophy and fibrosis of the gland does not influence the morphology of cancer cells (Yang et al, 1999).

RARE TUMORS OF THE PROSTATE

The cytology of a **rhabdomyosarcoma** was described by Moroz et al (1995). Caraway et al (1998) compared primary and metastatic **small cell carcinomas**. We have observed a case of **adenoid cystic carcinoma** with features identical to similar tumors of the salivary glands (see Chap. 32). **Endometrioid carcinomas** of prostatic utricle were discussed in Chapter 23. Masood (1991) stressed the frequency of nuclear creases in this tumor. See also comments above on ductal carcinoma of the prostate.

TESTIS AND EPIDIDYMISS

The early purpose of testicular needle biopsy was to investigate the **nature of palpable lesions** (Posner, 1905). This has remained one of the important applications of this technique. A more recent application of testicular aspiration biopsy is the **evaluation of spermatogenesis**. Thin needles (external diameter of 0.6 mm) are used and palpable lesions are aspirated without anesthesia. In the evaluation of fertility, however, local anesthesia is required.

ANATOMY AND CYTOLOGY OF NORMAL TESTIS

The testis is composed of numerous **seminiferous tubules** and **interstitial tissue**, surrounded by several connective tissue envelopes, including **the tunica vaginalis, lined by mesothelium**. Each seminiferous tubule is a folded, very long structure, wherein the maturation of spermatozoa takes place in several stages, starting with the most primitive cells (or **spermatogonia**). They undergo successive stages of maturation as **spermatocytes** that are transformed into **spermatids** and **spermatozoa**. During the spermatocyte stage, the cells undergo a cell division (**meiosis**) that reduces the number of chromosomes from the **diploid 46** to the **haploid 23, composed of 22 autosomes and one sex chromosome, either X or Y** (see Chap. 4). Thus, the sperm determines the sex of the product of conception, because all ova are

P.1276

provided with a single X chromosome. The outer lining of the tubules is provided by **columnar Sertoli cells**, forming a cytoplasmic network within which the process of maturation of spermatozoa takes place. Hormonally active, large **Leydig cells** are found in the interstitium of the testis.

Normal cellular constituents of the testis (spermatogonia, primary spermatocytes, spermatids, spermatozoa, Sertoli and Leydig cells) are observed in aspirates obtained for study of spermatogenesis. They are also observed if the needle is inadvertently introduced into normal parenchyma during the aspiration of a palpable lesion. For a detailed description of cytology of seminiferous tubules, see Zajicek (1979) and Schenck and Schill (1988).

Spermatogenic and Related Testicular Cells

Aspirates from the normal, sexually mature testis are dominated by spermatogenic cells. The most primitive of the cells, **spermatogonia**, have a round, central nucleus, with a small nucleolus. The cytoplasm is homogenous and has well-defined borders. In air-dried, MGG-stained smears, the spermatogonia may resemble lymphatoid blast cells and an inexperienced observer may suspect the presence of a **malignant lymphoma**. A more detailed scrutiny of the smear, however, will reveal numerous transitional cell forms, ranging from spermatogonia to spermatozoa (Zajicek, 1979; Papic et al, 1988).

The most common and readily recognizable are the **primary spermatocytes**. They have a long prophase and the nuclei are intensely stained due to reorganization of their chromatin into **thick prophase chromosomes** leading to the haploid cells (Fig. 33-18). The **secondary spermatocytes and spermatids** are characterized by smaller nuclear sizes (these are haploid cells) and condensation of chromatin. The **spermatozoa** have a small, oval, condensed nucleus and a long cytoplasmic tail.

Figure 33-18 Aspiration biopsy of testicle for evaluation of spermatogenesis. *A.* Early maturation arrest. The smear shows abundant large Sertoli cells with ample cytoplasm and primary spermatocytes, characterized by compact, hyperchromatic dark nuclei surrounded by clear, vacuolated cytoplasm. There is no evidence of mitoses in spermatocytes (compare with *B*). *B.* Late maturation (post-meiotic) arrest. In addition to Sertoli cells, the smear shows a normal number of primary spermatocytes, many showing mitotic activity, and spermatids, characterized by small, dark nuclei (*arrows*), but usually complete absence of mature sperm. (Both photos courtesy of Dr. Britt-Marie Ljung, San Francisco, CA.)

Sertoli Cells

These cells have a round, vesicular nucleus that contains a large nucleolus, surrounded by **abundant pale and vacuolated cytoplasm** with poorly defined cell borders (Fig. 33-18A). The cytoplasm is fragile and naked nuclei are common. These cells are scarce in normal adult testis but may become numerous if there is an arrest of spermatogenesis and in normal elderly men.

Interstitial or Leydig Cells

These hormone-producing cells play a critical role in sexual differentiation and maturation in males. An abnormality of Leydig cells may lead to severe endocrine disturbances (recent review in Liu et al, 1999). In smeared aspirates, these cells appear **singly or in clusters**. They are somewhat smaller than Sertoli cells and have a **central spherical or oval nucleus**. Some Leydig cells are binucleated. The abundant, irregularly delineated, usually eosinophilic, cytoplasm is finely granular. **Reinke's crystalloids** may be observed in the cytoplasm in the form of elongated rhomboid crystals (see Fig. 33-23). As with Sertoli cells, a relative **increase of Leydig cells** is found in aspirates from juvenile and atrophic testes.

ASSESSMENT OF SPERMATOGENESIS

Infertility in males may have numerous causes, many of which are related to testicular function. Malfunction may occur in various stages of spermatogenesis, described above. The causes of malfunction are complex and beyond the scope of this book.

- Spermatogenesis may be **completely absent** and neither precursor cells nor sperm are formed.

- There may be an **early arrest of spermatogenesis**: spermatogonia and primary spermatocytes are formed but do not undergo meiotic division (see Fig. 33-18A).
- There may be a **late arrest of spermatogenesis**: a meiotic division takes place in secondary spermatocytes but sperm formation does not take place (Fig. 33-18B).
- Sperm formation is normal but none are found in the semen because of a mechanical obstruction.

The term **azoospermia** is used clinically to describe the absence of spermatozoa in the semen.

The assessment of spermatogenesis has become even more important in recent years because new reproductive techniques, such as **intracytoplasmic sperm injection** into a harvested ovum, may be implemented with a single spermatozoon. Thus, the presence of even minimal spermatogenesis may be important to achieve reproductive success (Turek, 1998). Needle aspiration of the testes in azoospermic men has been used for assessment of spermatogenesis for many years (Obrant and Persson, 1965; Persson et al, 1971; Gottschalk-Sabag et al, 1993, 1995; Chao et al, 1997; Craft et al, 1997; Mahajan et al, 1999; Meng et al, 2001).

With the development of new methods of fertilization, it became very important to test **whether the needle aspirates offered equivalent information to open testicular biopsy**. This was tested on imprint cytology of testicular biopsies (Dusmez et al, 2001) and on May-Grünwald-Giemsa-stained smears of ejaculates (Amer et al, 2001). However, the most elaborate system of testing for spermatogenesis in infertile men was reported by Meng et al (2001). These authors reported a system of “**mapping**” **technique by performing multiple needle aspirations of a testis** at 5 mm intervals (from 2 to 11 per testis) and comparing the results with open biopsies. The smears were fixed in alcohol and Papanicolaou stain was used. In 87 men, the various forms of deficiency of spermatogenesis (**inadequate formation of sperm or hypospermatogenesis, early or late maturation arrest, absence of spermatogenesis**) were assessed on smears of aspirates by “**pattern recognition**.” The proportions of various stages of spermatogenesis, as outlined above, and the proportion of Sertoli cells were used to determine normal and abnormal maturation (see Fig. 33-18). The accuracy of the cytologic procedure, when compared with tissue biopsies, was from 91 to 97%. The absence of spermatogenesis was best documented when only Sertoli cells were seen in smears. It must be noted that, in some cases, infertility in men is caused not by abnormalities of maturation arrest but by **abnormalities in chromatin structure** in nuclei of spermatocytes, as documented by Perreault et al (2000) by flow cytometry. Another possible cause of infertility was the presence of an increased percentage of **deformed, round-headed** spermatozoa (Kalahanis et al, 2002).

Exposure to Radiation

Because the testis is exquisitely sensitive to radiation damage that may impair spermatogenesis, Perreault et al (2000) suggested that abnormalities of DNA ploidy, determined by fluorescent in situ hybridization (FISH), may be a sensitive index of exposure to radiation or, perhaps, other toxic agents, such as smoking. Although semen samples were used in this study, aspiration biopsy may be a better source of material in the future.

Inflammatory Lesions

Acute Orchitis

In acute orchitis, which often complicates other infections (e.g., influenza, mumps, pneumonia, cystitis), the testicle becomes painful, swollen, and firm. Such testes are rarely aspirated.

However, if performed, aspiration biopsy yields abundant material, mainly **fibrin, granulocytes, phagocytes, and cell detritus**. Such smears should be carefully inspected because, occasionally, **malignant neoplasms of the testis may be accompanied by acute inflammation**. The clinical history is the main guide to correct interpretation of the cytologic findings.

Chronic Orchitis

Acute orchitis may subside completely or may persist in chronic form. The yield of an aspiration biopsy in chronic orchitis is less than in the acute condition, mainly because of increased fibrosis of the testis. Variable degrees of degeneration and decrease of spermatogenic cells are found, as well as relative increase of Sertoli and Leydig cells. Variable numbers of lymphocytes, histiocytes, and plasma cells with scanty admixture of granulocytes are also present in the smears.

Granulomatous Orchitis

In addition to the cells found in chronic orchitis, aspirates from granulomatous orchitis (usually caused by tuberculosis) contain clusters of epithelioid cells and occasional multinucleated giant cells. It must be pointed out that **well-formed granulomas**, composed of epithelioid and giant cells, are commonly observed in **primary and metastatic seminomas** (see below).

Cystic Lesions

Hydrocele (hematocele) and **spermatocele** are the two most common conditions that can simulate a testicular tumor and from which fluid can be aspirated at needle biopsy.

Aspiration biopsy of **hydrocele** usually yields clear, amber-colored fluid. Centrifugation gives a scanty sediment consisting of mesothelial cells and lymphocytes. Occasionally, the aspirate is hemorrhagic, indicating that bleeding has occurred in the sac of the tunica vaginalis (**hematocele**). **Marked atypia of mesothelial cells**, mimicking a malignant tumor, may occur in hydroceles of long duration (see Chap. 27). The aspirate in **spermatocele** consists of variable amounts of milky fluid containing spermatozoa. Benign **squamous cysts** may also occur in the testes and may be confused with a well differentiated teratoma (see below). In aspiration smears of such cysts, only squamous cells and cell debris are observed.

P.1278

Because some malignant testicular tumors, particularly teratomas, may be partially cystic, the removal of fluid from a cystic lesion should be followed by careful examination of the affected testis. **If a residual mass is palpable**, it should be aspirated again or biopsied.

For description of **mesotheliomas of the tunica vaginalis testis**, see Chapter 26.

TUMORS OF THE TESTES

Tumors of the testes are classified, on the basis of their origin, into two main groups: **germ cell tumors** and **sex cord-stromal tumors**. The classification of germ cell and sex cord tumors is shown in Table 33-1. Rarely, **paraneoplastic encephalitis** has been observed in patients with testicular cancer, attributed to antibodies against proteins formed by the tumor (Voltz et al, 1999).

Germ Cell Tumors

Germ cell tumors comprise about 95% of all malignant testicular tumors. Sex cord stromal

tumors (Sertoli and Leydig cell tumors) are rare and usually benign. The common germ cell tumors are **seminomas, embryonal carcinomas, and teratomas. Contrary to the ovary, where nearly all teratomas are benign, all teratomas of the testis must be considered malignant.** These tumors may occur in **pure form or in various combinations.** In a series of 834 germ cell tumors, Nefzger and Mostofi (1972) classified 316 (38%) as **seminoma**, 123 (15%) as **embryonal carcinoma**, 59 (8%) as **teratoma**, and 3 (0.4%) as **choriocarcinoma**. The remaining 333 germ cell tumors were **combinations of various types**, the most common was embryonal carcinoma-teratoma (199 cases; 24% of all tumors), teratoma-embryonal carcinoma-seminoma (6%), embryonal carcinoma-seminoma (5%), and teratoma-serminoma (~2%). Combinations of various germ cell tumors with choriocarcinoma were found in the residual 3% of the series. These tumors can also develop in **undescended testes**.

TABLE 33-1 TUMORS OF THE TESTIS

Cell Origin and Histologic Presentation	Nomenclature in Testis
Germ Cells	
Primordial germ cells	Seminoma
Yolk sac vesicles, endodermal sinuses	Yolk sac tumor
Trophoblastic tissue	Choriocarcinoma
Multiple embryonic bodies	Polyembryoma
Embryonal cells in epithelioid structures	Embryonal carcinoma
Tissues of various origin and differentiation	Teratomas
	Immature
	Mature ^a
Sex Cord Stromal Cells	
Granulosa cells	Granulosa cell tumor
Sertoli cells and Leydig cells	Androblastoma
Sertoli cells	Sertoli cell tumor
Leydig cells	Leydig cell tumor

Granulosa cells and Sertoli cells

Gynandroblastoma

^a The tumor is malignant in the testis, but not in the ovary.

In the serum of patients with testicular germ cell tumors, markers such as placental alkaline phosphatase (PLAP), α -fetoprotein (AFP), and β -subunit of human gonadotropin (β -HCG) are often elevated. Although PLAP is usually elevated in pure seminomas, all markers may be elevated in other tumor types, in keeping with their mixed nature. The markers are very useful in the follow-up of treated patients. Their **persisting elevated level suggests that the tumor, or its metastases, have not been cured.**

Seminomas

Seminomas usually occur in young males, most commonly in teenage boys, and, with decreasing frequency, to the age of 40. Seminoma may be histologically classified as **typical, anaplastic, or spermatocytic**. Seminomas may also occur as a **component of testicular teratomas**. **Seminoma in situ** is a lesion confined to the seminiferous tubules (whence the tumor originates). **Patients with undescended testes are prone to seminomas** and, if the testes are surgically removed, they should be carefully examined for the presence of seminoma in situ (Halme et al, 1989). Basu et al (2002) reported several such cases.

Typical Seminoma

Histology.

Typical or classic seminomas in histologic sections are composed of a homogeneous population of neoplastic cells. The tumor cells have clear cytoplasm, large nuclei, each containing a single prominent nucleolus. **Glycogen** is demonstrable in cytoplasm. Mitotic figures are uncommon. The tumor is divided by thin, fibrous septa. The presence of **lymphocytes**, often forming large aggregates and sometimes germinal centers, is a common feature of these tumors. Another striking morphologic feature of this tumor, whether primary or metastatic, is the presence of **granulomas composed of epithelioid cells and Langhans'-type giant cells** (Fig. 33-19C).

Cytology.

The smears are cellular, showing a rather monomorphic population of dispersed or loosely clustered, **large neoplastic cells intermingled with lymphoid cells** (Fig. 33-19). This mixture of tumor cells and lymphocytes is quite characteristic of the tumor. The tumor cells have round or oval nuclei with a **peculiar, fine granularity of the chromatin** and conspicuous, often **multiple, and oddly shaped nucleoli**. The **cytoplasm** is scanty and usually frayed at the edges. Pyknotic nuclei and necrotic material are usually present.

P.1279

Figure 33-19 Typical seminoma of testis. *A,B.* Smears of a seminoma, one fixed and stained with Papanicolaou stain (*B*) and one stained with May-Grünwald-Giemsa (MGG) (*A*). The large, clear nuclei of the tumor with prominent nucleoli are best seen in *B*. In the MGG-stained smear, the nuclear detail is lacking but the background shows “tigering” (see Fig. 33-20C). There are a few scattered lymphocytes in the background. *C.* Histologic section of a typical seminoma. The lymphocytic component is not shown.

A **granulomatous reaction**, which is often seen in tissue sections, may be expressed in aspirates by the presence of **epithelioid cells and, occasionally, multinucleated giant cells** (Fig. 33-20A,B). In **air-dried smears** stained with one of the hematologic stains, the background of the smear often shows characteristic denser and lighter stripes, known as **the tigroid pattern** (Figs. 33-19A,B and 33-20C). The pattern is probably an artifact due to cytoplasmic fragmentation during smear preparation. **Placental alkaline phosphatase immunostain is usually positive in seminoma.**

Similar patterns may be observed in **metastatic seminoma**, usually located in the retroperitoneum, where the most important point of differential diagnosis is **large cell malignant lymphoma** (see Chaps. 31 and 40). Although lymphoma can be primary in the testis (see below), it is most often observed as metastatic disease. The presence of **lymphoglandular bodies** in FNA smears, and, most importantly, a positive stain with the **common lymphocyte antigen**, identify lymphomas, whereas the **PLAP reaction** identifies seminomas. Akhtar et al (1990) reported similarities in ultrastructure of seminomas and ovarian dysgerminomas (see Chap. 15).

Anaplastic Seminoma

Histology.

The histologic features of the tumor are similar to those seen in classic (or typical) seminoma, but the **nuclear pleomorphism is significantly more marked and the enlarged nucleoli are often multiple**. Mitotic figures are very uncommon. Usually, there are few lymphocytes in the tumor (Tickoo et al, 2002).

Cytology.

The tumor cells, usually numerous, are dispersed. Because of the fragile cytoplasm, they often appear as “**naked**” **nuclei** with only small wisps or cytoplasm attached. Small, loosely structured clusters of tumor cells can also be seen. The **cells are generally larger** than those of a typical seminoma. In contrast to typical seminoma, the **nuclei vary markedly in size and have irregular contours and coarsely granular, unevenly distributed chromatin**. The nucleoli are oddly shaped, prominent and often multiple.

P.1280

Mitotic figures may be observed. Breakdown of nuclear material in the form of DNA streaks may be noted. A few lymphocytes are usually present in the background (Fig. 33-21).

Figure 33-20 Special features of typical seminomas. *A* A poorly formed cluster of elongated, epithelioid cells, representing a granuloma. *B* A multinucleated giant cell. *C*. “Tigering,” seen in air-dried smears stained with May-Grünwald-Giemsa. Note the large nuclei of tumor cells, scattered lymphocytes, and a peculiar striped pattern in the background. (*C*: Courtesy of the late Dr. Törsten Löwhagen, Stockholm, Sweden.)

Spermatocytic Seminoma

Patients with this uncommon subtype of seminoma are usually **older** than those with other types. The prognosis is generally very good. Metastases rarely occur (Wheeler, 1989).

Figure 33-21 Anaplastic seminoma. *A.* Aspiration smear of metastatic tumor in the retroperitoneum. Note the bizarre tumor cells. Also present are capillary vessels. *B.* Testicular tumor composed of sheets of cancer cells showing significantly greater variability in configuration than typical seminoma.

Histologically, the tumor is composed of cells with round nuclei and moderate variation in cell size. The cytoplasm is dense and devoid of glycogen. **Gland-like structures** may be observed within the tumor. Lymphocytic infiltration and granulomas are absent.

Cytology.

The smears contain numerous **mononuclear tumors cells of variable sizes** sometimes arranged in clusters suggestive of adenocarcinoma (Fig. 33-22). Medium-sized cells are most numerous. The cytoplasm is scanty. Occasionally,

P.1281

large binucleated cells may be observed. The nuclei contain conspicuous nucleoli. The smears have a clean background. Neither lymphocytes nor other inflammatory cells are observed (Lopez and Aranda, 1989).

Figure 33-22 Spermatocytic seminoma in a 27-year-old patient. *A.* The smear shows cluster of cells of moderate size suggestive of gland formation. The cytoplasm is pale. The nuclei contain conspicuous nucleoli. *B.* The testicular tumor is characterized by formation of gland-like spaces by the small tumor cells. (Case courtesy of Dr. Jacek Sygut, Kielce, Poland.)

Embryonal Carcinomas

Histology

In its most common histologic presentation, this tumor is composed of large, anaplastic cells growing in solid sheets. However, glandular and papillary patterns are often seen. The tumor cells are pleomorphic. The cytoplasm is usually clear or faintly eosinophilic. Cell borders are often ill-defined. The nuclei are large, irregular, often vesicular, and provided with large, irregular nucleoli. The chromatin frequently appears in large clumps. Mitotic figures, often atypical, are numerous. This tumor often appears **in combination with other germ cell tumors** and may be part of a teratoma.

Cytology

The smears contain numerous large tumor cells of epithelial-type, occurring singly, but also forming **small or large, fairly cohesive sheets or clusters, sometimes in papillary or glandular configuration**. The background usually contains necrotic debris (see Chap. 26, describing the presentation of metastatic tumor of this type). The tumor cells have pleomorphic, often **vesicular nuclei with irregular nucleoli**. The cytoplasm is variable, often scanty and usually poorly preserved. The recognition of this tumor type and its separation from seminomas is usually rather simple because of the **presence of cell aggregates** that virtually never occur in seminomas, except in spermatocytic type (see Fig. 33-22). Air-dried smears, stained with May-Grünwald-Giemsa or related stains, often shows a **“tigroid” background, described for seminoma** (Linsk and Franzén, 1989).

Teratomas

Histology

These tumors are solid but **may form cysts**. Several types of tissue, representing **two or three embryonal layers**, are generally found in these tumors which, **contrary to their ovarian counterpart, are always malignant, regardless of the degree of differentiation**. The ectodermal layer, as a rule, is represented by squamous epithelium and neurogenic tissue, the endodermal layer by gastrointestinal and respiratory tissue, and the mesodermal layer by muscle, cartilage, and bone. A variety of other tumor types, such as **seminomas, embryonal carcinomas, and choriocarcinomas** may be associated with teratomas. The elevation of the serum levels of the neoplastic markers of germ cell tumors is common. The elevation of **β -subunit of human gonadotropin**, often observed in testicular teratomas, suggests the presence of **elements of choriocarcinoma** which, however, may be inconspicuous and difficult to find.

Cytology

At aspiration biopsy, pure teratomas usually are **hard on palpation** and often resist penetration by the needle. The yield of cells is most often small. **Cytologic diagnosis of tumor may be extremely difficult in such material**. It is for this reason that the number of cases described is very limited. The best account of these tumors is found in Linsk and Franzén's book (1989). When a **cystic area** of the tumor has been penetrated by the needle, the **fluid is usually nondiagnostic**. Palpation of the testis, after removal of the fluid, reveals a hard mass which, on repeated aspiration, yields scanty material composed of **fragments of epithelial structures, fibroblasts, or fragments of cartilage**. We have not observed any such cases.

When a teratoma is associated with **seminoma, embryonal carcinoma, or choriocarcinoma**, as is the case in about 30% to 35% of all such tumors, these components may predominate in needle aspirates because of their high cellularity and low cohesiveness. The **teratoma component, therefore, may be unrecognized**. This has some clinical implications, since survival rates are much higher in pure seminoma than in seminoma-teratoma, and are somewhat lower in pure embryonal carcinoma than for the combination of this tumor type with teratoma (Nefzger and Mostofi, 1972).

P.1282

Other Tumors and Tumorous Conditions

Yolk sac tumors of testis are extremely rare and do not differ from identical tumors of the ovary (see Chap. 16). The serum levels of α -fetoprotein may be elevated.

Leydig Cell Tumor

These usually benign tumors of **interstitial or Leydig cells** of the testis may occur at any age but are uncommon in the very young. The first manifestation of disease may be gynecomastia, caused by estrogens secreted by the occult tumors. An exceedingly rare **malignant Leydig tumor** with metastases was described by Powari et al (2002).

Histologically, the tumors are composed of clusters of large cells with eosinophilic cytoplasm and spherical, uniform nuclei.

In aspiration smears, the tumor cells are uniform and large, with sharply demarcated **eosinophilic cytoplasm**, that may contain brown **lipofusein** granules and elongated, rhomboid **Reinke's crystalloids**. Jain et al (2001) reported finding the crystalloid in the nuclei of tumor cells. We have also seen one such case courtesy of Dr. Subash K. Gupta (Fig. 33-23).

Sertoli Cell Tumors

These are very uncommon testicular tumors, composed of **tubular structures** resembling seminiferous tubules, but filled with Sertoli cells. The tumors may be calcified. Pettinato et al (1987) described the cytology of one such calcified tumor as composed of **large polygonal tumor cells** next to amorphous deposits of calcium. Terayama et al (1998) described "**coffee bean nuclei**" in a touch preparation of a Sertoli cell tumor, obviously not a specific finding.

Primary Testicular Lymphomas

Primary testicular lymphoma is a **disease of elderly males**. One or both testes can be affected. The tumor is usually a high-grade lymphoma that has **the propensity to form skin metastases, particularly to the lower abdominal wall and thigh**.

Figure 33-23 Leydig cell tumor with rod-like Reinke's crystalloids. The crystalloids are seen in the background of the smear in *A* and within cells in *B*. (Photos courtesy of Dr. Subash K. Gupta, Kuwait.)

Figure 33-24 Testicular lymphoma in an 83-year-old man. Note the dispersed lymphocytic cells showing variation in size.

The aspiration biopsy of the affected testis yields a monotonous, dispersed population of malignant cells of the lymphoid type, similar to that seen in lymph nodes (Fig. 33-24). The **differential diagnosis includes seminomas** that may have a somewhat similar cytologic appearance. However, the cells of seminomas are larger and have the peculiar nuclear appearance characteristic of this tumor (see above). Further, with the exception of the rare spermatocytic seminomas that may occur in older men, most seminomas are usually observed in much younger patients.

Leukemia

Leukemia, especially **acute lymphoblastic leukemia of childhood**, commonly involves the testis. This involvement may be found at the time of the first diagnosis or during clinical or subclinical relapses after treatment. For reasons unknown, spinal fluid and the testis are sanctuaries for leukemic cells that may persist in spite of effective chemotherapy (see Chap. 27). **Testicular relapses** may become a major problem in many of these patients. The diagnosis is usually established on clinical grounds. Occasionally, however, the diagnosis requires confirmation and the aspiration

P.1283

biopsy appears to be a safe and reliable alternative to an open biopsy in the evaluation of these patients (Rupp et al, 1987; Layfield et al, 1988; Akhtar et al, 1991).

Aspirates of leukemic infiltration of the testis are highly cellular, yielding numerous leukemic

cells (see Chap. 27). The morphology of these cells depends on the type of leukemia. Normal testicular elements (spermatogenic cells and Sertoli cells) may be seen in such aspirates, occasionally intermingled with leukemic cells.

Paratesticular Tumors

Adenomatoid tumor is the most common paratesticular tumor, usually localized in the epididymis. The tumor may also occur in the tunica albuginea or in the spermatic cord. This benign tumor, probably of mesothelial origin, is **composed of cords and rows of cells admixed with tubular and angiomatoid structures** in a fibrous stroma. We have not seen an aspiration biopsy of this tumor.

As described by others, the smears contain sheets of epithelial cells and clusters of monomorphic cells with round or oval nuclei and inconspicuous nucleoli. The cytoplasm is clear and vacuolated in Papanicolaou stain and stains pink with Giemsa stain. "Naked" nuclei and fragments of stroma can also be seen (Zajicek, 1979; Perez-Guillermo et al, 1989).

Desmoplastic small round cell tumor of tunica vaginalis testis was described by Lamovec and Zakotnik (2001). For description of histology and cytology of this tumor, see Chapter 26.

The Skin

HISTORICAL OVERVIEW

The skin and its adnexa are easily sampled by “shave” or excisional biopsies, which are usually interpreted by tissue pathologists. Therefore, cytologic techniques, which require special skills of sampling and interpretation, are not widely used. It is of historical interest, though, that the **term biopsy** was coined by a French dermatologist, Ernest Besnier in 1879 (Besnier, 1879; Nezelof et al, 2001). Also, the German dermatologist, Hirschfeld (1912) first reported the **use of a small caliber (thin or fine) needle for cell sampling in a case of malignant lymphoma of the skin**.

Direct scrape smears are a **much neglected field of cytologic diagnosis of skin lesions**, although there is ample evidence that this approach is **rapid, accurate and cost-effective** (Zoon and Mali, 1950; Hitch et al, 1951; Wilson, 1954; Urbach et al, 1957; Goldman et al, 1960; Graham et al, 1961; Selbach and Heisel, 1962; Brown et al, 1979; Canti, 1984). To be sure, “scrape” cutaneous cytology requires skilled and dedicated practitioners with considerable expertise in the clinical and cytologic aspects of various cutaneous disorders, ranging from **infectious disorders, bullous disease (such as pemphigus vulgaris), to benign tumors and other benign conditions of adnexal glands to cancer**. **Fine (thin) needle aspiration biopsy (FNA)** is used by a small number of clinicians and cytopathologists to the diagnosis of palpable nodular lesions (Daskalopoulou et al, 1998; David et al, 1998). As in other organs, a limitation of this approach is the loss of the tissue patterns that some observers consider essential for diagnosis of many skin lesions (Ackerman, 1997).

In this chapter, the cytologic presentation of common disorders of the skin that may be diagnosed either by direct scrape cytology or by FNA, will be discussed.

BRIEF RECALL OF HISTOLOGY

The skin consists of keratinized squamous epithelium or **epidermis** and the underlying connective tissue or the **dermis** (see Fig. 5-2). The epidermis, which is similar to other squamous epithelia, contains antigen-presenting cells or the **Langerhans' cells** and the endocrine **Merkel cells**. The dermis contains the **sweat- and sebaceous glands and the pilary apparatus**, i.e., hairs and hair follicles. All the components of the skin may be affected either by **inflammatory disorders** or by **neoplastic disorders** that may be either benign or malignant.

Methods of Sampling

Scrape Smears

Canti (1984) advocated the use of a **double edge dissector**, a lightweight instrument that can

be used for removal of **scrape samples** and their spread on glass slides (Fig. 34-1). A variety of **curettes**, or even simple **scalpel blades**, may also be used for this purpose. In some cases, the layer of keratinized superficial cells must be removed from the surface of the lesion. Canti (1984) advocated the preparation of **two smears**, one fixed in alcohol for processing with Papanicolaou stain, and one unfixed, stained immediately with **methylene blue or Diff-Quik** stain (Dade Behring Inc., Deerfield, IL) for immediate microscopic diagnosis. In many instances, the rapidly stained smear is adequate for diagnosis and saves much time to the patient and the dermatologist who can initiate treatment without delay. Several examples of the latter techniques can be found in

P.1287

this chapter, courtesy of Dr. G. Canti. The stain preparation techniques are discussed in Chapter 44.

Figure 34-1 Curette used by Canti for sampling of skin lesions (Canti, 1984).

Aspiration Biopsies (FNA)

For aspiration biopsies (FNA) of skin or subcutaneous nodules, a very **small caliber needle** (gauge 22 to 25), with or without syringe, can be used. For description of aspiration techniques of superficial skin nodules, see Chapter 28. Smear preparation may be the same, as outlined above for scrape smears. Nearly all of the recent reports are based on aspiration biopsies of palpable, nodular lesions of the skin and subcutaneous tissues (summaries in Koss et al, 1992; Layfield and Glasgow, 1993; Dey et al, 1996).

INFLAMMATORY DISORDERS

The skin is the site of numerous inflammatory disorders that require clinical recognition and sometimes skin biopsies for diagnosis. Cytologic approaches to this large group of diseases have not been explored, except for infectious disorders.

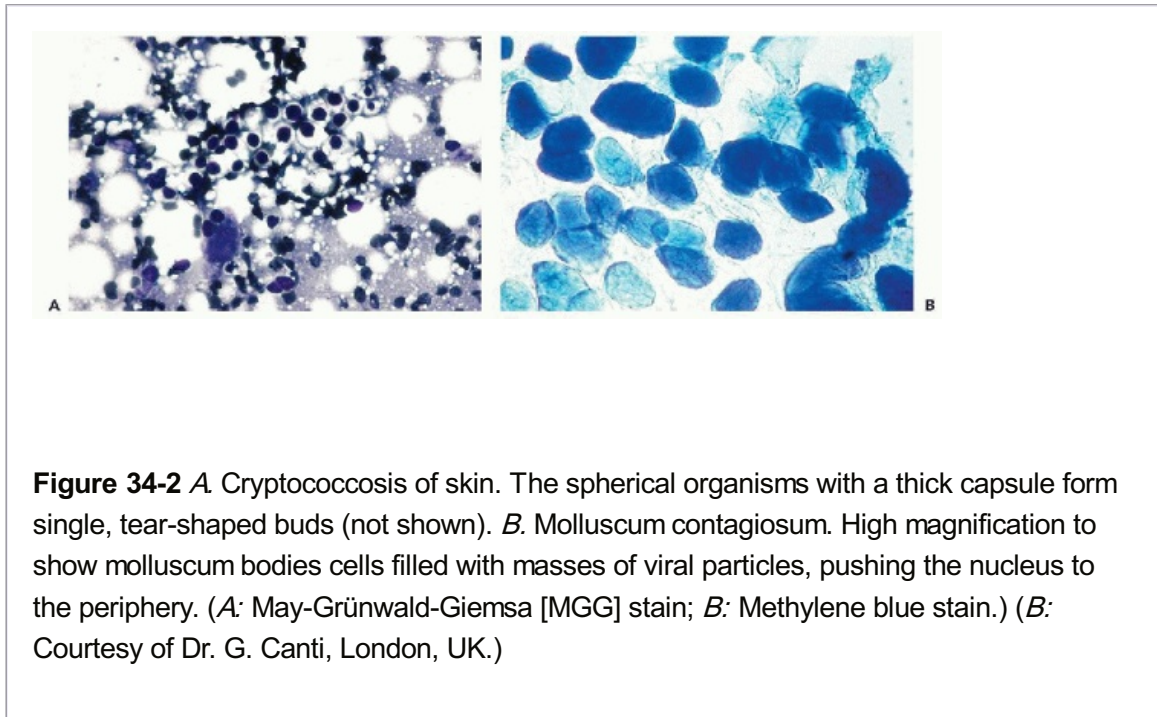

Infectious Disorders

Fungal and Parasitic Infections

Direct smear preparations for infectious disorders of the skin, especially in scaly skin lesions, have been in use for many years. The diagnosis of **fungus infections** of the skin (dermatophytosis) is readily accomplished in **direct smears** using a few drops of potassium hydroxide (KOH) to clear the cornified cells (squames) scraped from the surface of a lesion.

The smears may be inspected unstained or stained with methylene blue or another rapid stain.

Fungal hyphae and **yeast forms** (such as *cryptococcus* or *blastomyces*) may be demonstrated.

Aspiration biopsies of nodular lesions of the skin caused by fungal organisms have been reported. Thus, **blastomycosis** was reported by Desai et al (1997) and **histoplasmosis** by Stong et al (1994). We observed a case of **cryptococcosis** of the skin in the form of a palpable nodule in a patient with AIDS (Fig. 34-2A). The morphologic features of these organisms are discussed in Chapter 19.

Some **parasitic diseases** of the skin, such as the mite *Sarcoptes scabiei* causing a severe skin itch known as **scabies** and *Leishmania donovani*, may also be identified in scrape smears (Baez-Giangreco et al, 1989; Koss et al, 1992). Kapila and Verma (1989) and Koss et al (1992) described **filariasis** of the skin. **African trypanosomiasis (sleeping sickness)** can also be diagnosed by aspiration of lymph nodes as first reported by Graig and Gray in 1904. The disease produces **ulcerated skin lesions (chancre)**. The diagnosis can be established on fluid from the chancre (Case Records of the Massachusetts General Hospital, Case 20-2002). The harmless small parasite, *Demodex folliculorum*, a common inhabitant of follicular infundibula of face, can also be recognized in scrape smears because of eight protrusions known as “**sucker feet**” and a **striated abdomen** (Canti, 1984). Kamal and Grover (1995) reported on several cases of **cysticercosis** diagnosed by aspiration of subcutaneous nodules. For a detailed discussion of leishmaniasis and cysticercosis, see Chapter 19.

Bacterial Infections

Tuberculosis of the skin (known as **lupus vulgaris**) is now-a-days uncommon. Canti (1984) reported the presence of carrot-shaped **epithelioid cells and occasional giant cells**, accompanied by inflammatory exudate, in scrape smears. The same observer reported finding epithelioid cells in the uncommon skin manifestations of **sarcoidosis**. See Chapter 19 for a detailed discussion of these disorders.

The acid fast rods *bacillus leprae* (**leprosy**), which may

be very numerous in skin lesions of the lepromatous form, can also be recognized in aspiration smears (Singh et al, 1996). Other applications of this technique are to **subcutaneous abscesses or infected cutaneous cysts** that may also yield a diagnosis by this simple, rapid and inexpensive procedure. A case of **intramuscular bacillary angiomatosis** was diagnosed on thin needle aspiration of a subcutaneous mass in a patient with AIDS (Sanchez and Rorat, 1996). Besides inflammatory cells, the aspiration smears in this case contained clumps of amphophylic granular material containing small bacterial rods demonstrated by silver stain. The organisms belonging to the genus *Rochalimacea* (now *Bartonella*) are also involved in **cat scratch disease** (see Chap. 31).

Viral Disorders

Molluscum Contagiosum

The large size **pox virus** infects hair follicles and typically produces multiple umbilicated lesions on the surface of the skin which, however, when single, may mimic a basal cell carcinoma. Smears of these lesions are easily obtained by squeezing the lesion and expelling its core on a slide that may be immediately examined after methylene blue staining (Canti, 1984). The smears show a large number of “**molluscum bodies**,” which are **squamous cells filled with masses of viral particles, displacing the nucleus to the periphery** (Fig. 34-2B). For comments on **herpesvirus** infection, see below.

BULLOUS DISEASES OF THE SKIN

Tzanck (1947) was the first to advocate the use of fresh smears for differential diagnosis of **vesiculo-bullous diseases, e.g., bullous pemphigoid, herpesvirus infection, or toxic epidermal necrolysis**. As discussed at length in Chapters 19 and 21, **pemphigus vulgaris** and its variants, known as **pemphigus foliaceus** and **pemphigus vegetans**, can be recognized because of numerous, dispersed, peculiar **intermediate squamous cells with large nuclei and nucleoli (acantholytic cells of Tzanck)** (Fig. 34-3). The presence of **bizarre multinucleated cells** was emphasized by Tzanck but we have not observed them in our material, nor did Canti. Other forms of pemphigus, wherein the bullae are formed within the epidermis, such as **familial pemphigus**, may also show a small number of similar cells (Canti, 1984). For description of cytologic findings in **Darier's disease** (that may also occasionally form skin vesicles), see Chapter 21.

Figure 34-3 Pemphigus vulgaris. A Tzanck's cells with large, pale nuclei and prominent, sometimes multiple nucleoli. B. Cross-section of a skin vesicle containing Tzanck's cells.

(Case courtesy of Dr. G. Canti, London, UK.)

Herpesvirus type I or II and herpes zoster infections form painful vesicles. The cell changes caused by these viruses are discussed at length in Chapter 10. **Toxic epidermal necrolysis and other vesicle-forming lesions** do not show any of these disease-specific changes but do show necrosis and inflammation (Canti, 1979, 1984).

RARE BENIGN DISORDERS

Amyloidosis

Blumenfeld and Hidebrandt (1993) reported on aspiration of **abdominal fat for the diagnosis of amyloidosis** in 17 patients in whom amyloidosis was clinically suspected. The presence of amyloid was documented in 8 patients by apple-green birefringence of amyloid stained with congo red.

Subcutaneous Fat Necrosis of Newborns

Subcutaneous fat necrosis occurs in infants subjected to various forms of trauma (Silverman et al, 1986). Gupta et al (1995) established this diagnosis in aspirated material by observing **necrotic fat cells and crystals of fatty acids**.

Endometriosis

Endometriosis in the form of **nodules** most often occurs in the abdominal wall in **young women** in the area of the **umbilicus** or in **laparotomy scars**. **Subcutaneous endometriosis** is an especially important point of differential diagnosis with primary or metastatic tumors (Leiman et al, 1986).

P.1289

Figure 34-4 Endometriosis occurring in the scar of a Caesarian section. A. Clusters of small, spindly stromal cells (*left*) and larger glandular cells (*right*). B. Higher power view of a compact cluster of stromal cells. C. Higher power view of glandular cells forming a “honeycomb” cluster. Small nucleoli occur in some of the nuclei, a common finding in

proliferative phase (see Chap. 13). *D.* Cell block of the lesion showing endometrial glands and stroma. (Case courtesy of Dr. J. Amberson, Dianon Systems, Stratford, CT.)

The aspirate usually contains **two families of cells: larger cells, representing the lining of the endometrial glands, and smaller, spindly cells of endometrial stroma** (Fig. 34-4).

Unless close attention is paid to the differences between these two cell populations, **erroneous diagnoses of metastatic adenocarcinoma** have been known to occur, sometimes with disastrous results (Ashfaq et al, 1994). The differential diagnosis becomes even more difficult if the **stromal cells are decidualized**, i.e., become large, decidual cells with abundant eosinophilic cytoplasm, as described by Berardo et al (1992). The knowledge of clinical history is essential in avoiding such errors.

PRIMARY NEOPLASMS

The application of cytologic techniques to **tumors of the skin and skin adnexae** is a natural extension of existing diagnostic procedures. In some institutions, **scrape preparations** have been found to be of value in **rapid and inexpensive** assessment of suspect neoplastic skin lesions (summary in Canti, 1984). Palpable nodular skin nodules may be sampled by aspiration with the help of very small caliber needles.

Benign Neoplasms

Seborrheic Keratoses

These soft, brown, elevated benign lesions of the sun-exposed skin are usually recognized clinically and rarely need biopsy confirmation. Histologically, the lesions show a proliferation of basal squamous cells with formation of small cystic areas filled with keratin. Basal cell and, very rarely squamous cell carcinomas, may develop in seborrheic keratosis; such lesions may become ulcerated and indurated. The diagnostic procedures of these rare lesions are the same as for carcinomas, described below. Canti (1979) described the smears as composed of nucleated and anucleated squamous cells without specific features.

Benign Tumors of Skin Adnexa

Benign and malignant tumors of the endocrine and apocrine sweat glands, hair or piliary apparatus are uncommon and show a wide spectrum of histologic patterns (Wick et al, 1985). The benign tumors are occasionally aspirated to rule out a primary or metastatic malignant tumor. Layfield and Mooney (1998) reported a case of a benign **hidradenoma** of the skin. We have seen a misleading case of **clear cell hidradenoma** in a young woman with a history of treated adenocarcinoma of the uterine cervix that was thought clinically

P.1290

to be a metastasis. The aspirate contained small epithelial cells with hyperchromatic nuclei occurring singly and in clusters (Fig. 34-5A-C). The clear cytoplasm of some of the cells contributed to the erroneous diagnosis of metastatic adenocarcinoma. Excisional biopsy of the nodule disclosed a clear cell hidradenoma (Fig. 34-5D). Courtesy of Dr. G. Canti, we also examined a smear of an **adenoma of a sebaceous gland**. The smear contained a cluster of large cells with faintly granular, abundant cytoplasm, resembling fat cells (Fig. 34-6).

Figure 34-5 Clear cell hidradenoma mimicking metastatic adenocarcinoma. A-C. The aspirate contained spherical or cuboidal cells in small and large clusters. The nuclei, although spherical, were hyperchromatic. The cytoplasm of most cells was clear. **D.** Histologic section of the encapsulated tumor, documenting the diagnosis of hidradenoma.

Fat-containing tumors, known as **xanthogranulomas**, and occurring mainly in infants and children, have been reported (Janney et al, 1991). Besides multiple macrophages, the lesions contained multinucleated giant cells (Grenko et al, 1996).

Pilomatrixoma (Calcifying Epithelioma of Malherbe)

These tumors, which occur mainly but not exclusively in young people, form chalky-white subcutaneous nodules, usually located on the face, neck, or upper extremities, sometimes underneath pigmented skin. The cytology of this tumor was first described in needle aspirates by Woyke et al (1982). The aspirates of these tumors contain **small basophilic cells, singly and in clusters**, admixed with **nucleated and anucleated squames**, the latter forming clusters of yellowish “ghost” cells. **Calcified material and foreign body giant cells** round out the spectrum of features (Fig. 34-7). Numerous errors of diagnosis have been committed in the past **mistaking pilomatrixoma for squamous carcinoma** (Gomez-Aracil et al, 1990; Koss et al, 1992; Domanski and Domanski, 1997). In recent reports, the features of pilomatrixoma have been better recognized and no errors of identification were made (Viero et al, 1999).

Figure 34-6 Sebaceous adenoma. The cell cluster is composed of large cells with faintly granular cytoplasm, resembling fat cells. (Courtesy of Dr. G. Canti, London, UK.)

P.1291

Figure 34-7 Pilomatrixoma of the upper eyelid. *A-C.* Aspirate, high magnification. *A.* A cluster of tumor cells with scanty cytoplasm and large vesicular nuclei of fairly even sizes with distinct nucleoli. *B, C.* Tumor nuclei stripped of cytoplasm. Note the distinct large nucleoli and evenly distributed chromatin. Some variation in nuclear size may be seen. *D.* Tissue section. The epithelial portion of the tumor consists of cells with vesicular nuclei and distinct nucleoli. There is a transition to an area of shadow cells and amorphous debris (*bottom*) with pyknotic nuclei (high magnification). (From Woyke S, Olszewski W, Eichelkraut A. Pilomatrixoma. A pitfall in the aspiration cytology of skin tumors. *Acta Cytol* 26:189-194, 1982.) (Reprinted from Koss et al, 1992.)

P.1292

Other Benign Tumors

From time to time, other benign tumors of soft parts may present as skin nodules. Housini and Dabbs (1990) reported a case of a benign **perineuroma** in a child. We observed **nodular fasciitis**, **infantile fibromatosis**, **benign fibrous histiocytoma** and **granulation tissue**, all mimicking skin tumors (Koss et al, 1992). The cytologic presentation of these tumors is discussed in Chapter 35.

Common Malignant Tumors

Basal Cell Carcinoma

Clinical Data and Histology

Basal cell carcinoma is, by far, the most common malignant neoplastic lesion of the skin. The tumors occur most often on skin exposed to sun, particularly in areas of **solar keratoses** which must be considered as **precancerous lesions** (see below). The tumors are recognized clinically because they form an elevated area of redness or a pearl-white nodule on the surface of the skin.

Figure 34-8 Basal cell carcinoma. A. Scrape smears of the tumor yield cohesive anastomosing sheets of small cells with peripheral, palisade-like arrangements. B, C. Cohesive sheets of small, monotonous tumor cells. Small nucleoli are seen in C. D. Histologic appearance of a typical basal cell carcinoma.

Histologically, the tumors, derived from the basal layers of the epidermis, are composed of solid, **anastomosing sheets or strands of uniform small cells with spherical nuclei and scanty cytoplasm**, that usually show peripheral palisading (Fig. 34-8D). **Variants** of basal cell carcinoma include **melanin-containing pigmented lesions** that may clinically mimic malignant melanomas, lesions with elongated, **spindly cells**, lesions with a **squamoid component**, and rare lesions with a **glandular component** sometimes mimicking adenoid cystic carcinoma. Regardless of histologic patterns, basal cell carcinoma usually grow locally, sometimes forming **large, ulcerated lesions** (rodent ulcer). Rarely, the tumor may form metastases.

Cytology

Scrapes or thin-needle aspirates of this group of tumors may yield characteristic **cohesive, sometimes anastomosing, usually flat sheets or clusters of various sizes**, composed of **small epithelial cells with scanty cytoplasm**. The **somewhat elongated, sometimes columnar, peripheral cells usually form a palisade** (Fig. 34-8A). Contrary to normal epidermis, intracellular bridges (desmosomes) are absent in basal cell carcinoma. **Nuclear pleomorphism is usually**

P.1293

slight, although visible nucleoli, single cell necrosis, and mitotic figures may occur (Fig. 34-8B,C). **Variants of basal cell carcinoma** may show phagocytized **melanin** pigment, **elongated tumor cells**, or the presence of **mucin** in the rare **glandular subtype**. However, the basic structure of cell clusters is the same. Essentially, similar features were reported in **aspirated samples** of primary and in the very uncommon **metastatic basal cell carcinoma** (Malberger et al, 1984; Garcia-Solano et al, 1998; Henke et al, 1998).

In aspiration biopsies of skin nodules, the **differential diagnosis** includes **benign and malignant tumors of the sweat glands, such as syringoma, or of piliary apparatus, such as trichoblastoma, trichoepithelioma**, etc. that are morphologically very similar to basal cell carcinoma (Wick et al, 1985; Varsa and Jordan, 1990; Layfield and Glasgow, 1993; Dey et al, 1996). The cytologic differential diagnosis in such cases may be much more difficult, if not impossible. It must be stressed, however, that contrary to the superficial, visible basal cell carcinomas, the tumors of sweat glands and the piliary apparatus are **dermal** and, therefore, not visible on the surface of the epidermis, unless ulcerated, and not accessible to scrape cytology.

Squamous Carcinoma

Clinical Data and Histology

Squamous carcinomas of the skin are much less common than basal cell carcinomas. The lesions occur mainly in sun-exposed areas but may occur anywhere, particularly in older patients. In **pipe smokers**, lips may be the site of tumors. In some countries, squamous carcinoma of the **penis** is fairly common (Cubilla, 1995). A peculiar form of low-grade **verrucous carcinoma of the penis is the Buschke-Loewenstein giant condyloma**, discussed in Chapter 11 (see also Schwartz, 1990). The role of **human papillomavirus infection** in the genesis of squamous carcinoma of the skin has received much attention since the observation that **epidermodysplasia verruciformis** (Lewandowsky-Lutz disease), a congenital skin disorder leading to squamous carcinoma, has been associated with this virus (Majewski and Jabłońska, 2002; Majewski et al, 1997). The role of this virus in cancer of the penis is the subject of an ongoing debate (recent summary in Dillner et al, 2000).

Figure 34-9 Squamous cell carcinoma. *A,B.* Scrape or aspiration smears contain keratinized squamous cells, either with relatively slight nuclear abnormalities (*A*), or marked nuclear enlargement and hyperchromasia (*B*). *C.* Cancer cells in methylene blue-stained smear. *D.* An example of squamous cell carcinoma with mitotic activity. (*C*: Courtesy of Dr. G. Canti, London, UK.)

In advanced stages, squamous carcinomas present as ulcerated, indurated lesions, often with a central crater. Contrary to basal cell carcinoma, squamous cancer of the skin is fully capable of forming **distant metastases**.

Histologically, the tumors may show varying degrees of differentiation, ranging from **fully differentiated keratinized tumors** forming numerous squamous pearls, to **poorly differentiated tumors** composed of small or spindly cells with only occasional formation of keratinized areas or squamous "pearls" (Fig. 34-9D).

P.1294

Cytology

Contrary to basal cell carcinoma, squamous cancers **do not form cohesive clusters of small cells**. The cancer cells are **much larger, dispersed**, and forming only small, loosely structured clusters. In fully invasive squamous carcinoma, the cytologic features depend on the degree of tumor differentiation. In well-differentiated cancers, **large squamous cells with large pyknotic nuclei and keratin shells ("ghost cells")** are common, as shown in Figure 34-9A. In some of these cancers, the **cancer cells with smaller nuclei and abundant cytoplasm may mimic normal squamous cells**, except for the heavily keratinized cytoplasm. In **poorly differentiated tumors**, the cancer cells are smaller, showing only occasional keratin formation in the cytoplasm (Fig. 34-9B,C). In such cases, the precise identification of tumor type may be difficult.

The **differential diagnosis** includes **basal cell carcinomas with squamoid features**, characterized by cohesive clusters of cancer cells with only focal keratin formation (Koss et al, 1992) and **keratoacanthomas**, usually benign, self-healing lesions, occurring mainly on the skin of the face (Canti, 1984). However, Hodak et al (1993) described three patients with solitary keratoacanthoma with metastases and considered the lesion to be a form of squamous carcinoma. Cytologically, the two lesions cannot be differentiated from one another in scrape smears (Fig. 34-10). There is no reported experience with keratoacanthoma in aspirated samples but it is likely that the difficulty of recognition may be the same. The cytology of **epidermal inclusion cysts** may also be misleading (Layfield and Glasgow, 1993; Biernat and Kordek, 1996; Daskalopoulou et al, 1998). In these lesions, **squamous cells**, singly and in small clusters, may show **nuclear atypia** and may be mistaken for squamous carcinoma, as is the case with **branchial cleft cysts** (see Chap. 30).

Perhaps the most important point of cytologic differential diagnosis is **pilomatrixoma (calcifying epithelioma of Malherbe)**, as discussed above and illustrated in Fig. 34-7.)

Figure 34-10 Keratoacanthoma. *A.* These benign lesions are more rapidly growing but mimic low-grade squamous cell cancer. *B.* Smear from the center of such a lesion showing squamous cells with minimal nuclear enlargement. (*A.* Courtesy of Dr. G. Canti, London, UK.)

Precancerous Lesions of the Epidermis

Solar Keratoses

Sun-exposed and damaged areas of the skin are prone to the development of precancerous lesions that are globally named **solar (actinic or senile) keratoses**. The lesions are clinically visible in the form of areas of redness, with superficial scaling. Histologically, the epidermis may show either hypertrophy or atrophy with scattered nuclear abnormalities of epithelial cells. The lesions may progress to **basal or squamous carcinoma**. Lever (1967) considered the lesion to be a “½ grade of a squamous carcinoma,” a view now widely shared by other dermatopathologists. The natural history of these lesions is difficult to ascertain as most of them are now being treated before cancer develops.

Cytology

Although **solar keratoses** should be a target of cytologic studies, as are precancerous lesions of other organs, there is very limited experience with these lesions. Canti (1984) observed that scraping of solar keratoses was **not very productive**, yielding only keratinized superficial squamous cells and occasionally cells from the deeper epithelial layers that he designated as “acanthotic cells.” Nuclear abnormalities that would be crucial in proper classification of the smears were rarely visible, most probably because they occur mainly in deeper epithelial layers.

Bowen's Disease

This disorder is represented by multiple, somewhat elevated areas of redness occurring on areas of the skin **not exposed to sunlight**. On histologic examination, the lesions show marked abnormalities of epithelial cells of the epidermis in the form of **nuclear enlargement, hyperchromasia, and numerous mitotic figures**. The term **carcinoma in situ** of the skin or **intraepidermal neoplasia** (which on the penis is known as **erythroplasia of Queyrat**) have been applied to these lesions which may progress to invasive squamous cancer if untreated (Gerber, 1994; Sober and Burstein, 1995). Similar lesions may occur in a congenital disorder

P.1295

known as **epidermodysplasia verruciformis** which is associated with infection with human papillomavirus of various types (Majewski and Jabłońska, 2002; Majewski et al, 1997). Also see comments above and Chapter 11.

Cytology

The experience with cytologic presentation of this disorder is limited to a very few personal cases observed over a period of many years. Scrapes of Bowen's disease show **nuclear abnormalities in small squamous cells, identical to those observed in high-grade squamous intraepithelial lesions of the uterine cervix** (see Chap. 11). These anecdotal observations clearly deserve further investigations as they may represent a good approach to the diagnosis of important preneoplastic lesions of the skin, without the trauma of multiple biopsies or the “wait and see” approach.

Malignant Melanoma

Clinical Data and Histology

Malignant melanomas are the **most lethal cancers** of the skin that occur mainly in fair-skinned people in areas exposed to sun (review in Woodhead et al, 1999). Most, but not all, of these tumors are pigment-producing. Most melanomas develop from melanocytes in the lower layers of the epidermis, sometimes in association with pre-existing **pigmented nevi** but more commonly as a spontaneous event. The melanocytic cells at the epidermis-dermis junction are transformed and become ballooned and acquire nuclear abnormalities in the form of **enlargement and prominent nucleoli**. The junctional change in the superficial form of melanoma is known as **lentigo maligna**. The most dangerous and common histologic forms of melanoma are those with **pleomorphic and large polygonal or spindle cells**, associated with rapid growth, the so-called “**nodular**” melanomas, although variants, such as nevus-like or “**nevoid**” **small melanomas, balloon cell and giant cell melanoma**, may also metastasize and kill.

Melanomas metastasize to **regional lymph nodes** but may also form blood-borne distant metastases **to the central nervous system, lung, gut, and liver** without any intermediate stops, sometimes many years after the removal of the primary tumor.

The **prognostic factors** in primary skin melanoma were studied by Clark et al (1969) and by Breslow (1970) who observed that **tumor thickness** was an important indicator of behavior. It was subsequently noted that **ulceration, proliferation index** (Balch et al, 2004) and **mitotic rate** (Sviatoha et al, 2002; Azzola et al, 2003) were also of predictive value. Biopsies of **sentinal regional lymph nodes** were also found to be of assistance in assessing the prognosis of the tumor (Essner et al, 1999).

It is evident that early diagnosis of malignant melanoma may be of critical value to the patient. Therefore, most clinically suspicious pigmented skin lesions are excised to determine their nature and, if malignant, their stage. The staging of the primary tumor is based on depth of invasion with **melanoma in situ** classified as Tis and tumor infiltrating the dermis for over 4 mm as stage T4. To our knowledge, the value of cytologic techniques in the discovery of early tumors has not been tested.

Cytology

There is relatively limited experience with cytologic diagnosis of **primary malignant melanoma** of the skin. Canti (1984) described the use of **scrape smears of suspicious pigmented lesions** of the skin and emphasized the **ease** with which cells of malignant melanoma can be removed from the surface of the lesions. Canti also stressed that this technique of diagnosis is **safer for the patient** than a tissue biopsy that may conceivably contribute to the spread of the tumor (Fig. 36-11A,B).

Experience with **aspiration biopsies** of **primary malignant melanoma** of the skin is also very limited (Woyke et al, 1980; Koss et al, 1992). By the time these tumors develop to the size necessary to permit aspiration biopsy sampling, many measure **5 mm or more** in thickness and may already have metastasized. Nearly all of the aspiration biopsy data reported in the recent literature pertains to metastatic melanoma (Rodrigues et al, 2000). Although distinguishing primary from metastatic melanoma is not possible in the aspirated sample, there is some **staging value** for patients with melanoma if a **new metastasis** can be documented

(Kline and Kannan, 1982). On the other hand, patients with a **prior diagnosis of malignant melanoma may develop nodular lesions that are benign** or metastases from another primary tumor. FNA is an excellent mode of triage among these lesions (Rodrigues et al, 2000). The target organs, besides the skin, include the liver, lung, intestine or central nervous system (see also comments on eye melanoma in Chapter 41).

Malignant melanoma is notorious for the **great variability of its cytologic presentation** and may **mimic almost any malignant tumor**, as has been repeatedly emphasized in various chapters of this book. The common denominator of most, although not all, tumors is the presence of **melanin pigment in tumor cells**. The pigment may be **dispersed and finely or coarsely granular, obscuring other features of the cells**. Still, the diagnosis must be based on **malignant features of the cells** because the presence of pigment alone may be **misleading**. The chief culprit is **melanin pigment phagocytized by macrophages, as this may occur in a variety of skin disorders not related to malignant melanoma**. Basal cell carcinomas and other lesions may occasionally shed pigment-containing cancer cells.

The principal cytologic feature of malignant melanoma is the presence of **cancer cells of variable sizes and configuration, provided with large nuclei, prominent, often multiple large, irregularly-shaped nucleoli, and large intranuclear cytoplasmic inclusions, a common feature in this group of tumors** (Fig. 34-11C,D). **Multinucleated giant cells, elongated spindly cells, and cells with vacuolated cytoplasm, may be observed** (Canti, 1984; Koss et al, 1992). The most prominent vacuolization of the cytoplasm occurs in the so-called **balloon cell melanoma** and such cells may be mistaken for cells of **metastatic adenocarcinomas** (Koss et al, 1992; Tsang et al, 1993). In a small percentage of cases, cells with **rhabdoid**

P.1296

features may occur. These cells are large, have **large peripheral nuclei**, large **nucleoli**, and **eosinophilic cytoplasmic inclusions**, best seen in Papanicolaou stain (Slagel et al, 1997). As is so common with other tumors, **nuclear grooves** may also be observed in cells of malignant melanoma (Rollins and Berardo, 1998).

Figure 34-11 Malignant melanoma of skin. A,B. A case of early melanoma diagnosed by scrape smear of the pigmented skin lesion. A. The pigmented tumor cells have large,

clearly abnormal hyperchromatic nuclei. *B*. The corresponding skin lesion is a superficial melanoma with junctional change. *C,D*. In another case, high magnification showing bizarre pigmented spindly cancer cells (*C*) and melanoma cells with large nuclei, many containing sharply demarcated clear zones, the intranuclear cytoplasmic inclusions (*D*). (*A,B*: Courtesy of Dr. G. Canti, London, UK; *C,D*: Courtesy of Prof. S. Woyke, Warsaw, Poland.)

In the absence of pigment, the cells of **amelanotic malignant melanoma** may be mistaken for metastatic carcinoma or even large cell lymphoma (Gupta and Lallu, 1997). The documentation of the true nature of the cells may require immunocytologic confirmation (see Chap. 45).

Dysplastic Nev

Dysplastic nevi are common pigmented lesions of the skin with “fuzzy” borders, usually more than 5 mm in diameter. Histologically, the lesions show a proliferation of melanocytes at the base and within the epithelium. The lesions confer a markedly increased risk of malignant melanoma (Naeyaert and Broches, 2003). DNA ploidy analysis of these lesions failed to differentiate between potentially benign and potentially malignant dysplastic nevi (Sanguenza et al, 1993).

There is virtually no experience with **cytology** of these lesions, except for limited data provided by Canti (1984). Energetic scraping of the surface resulted in **cohesive clusters of epithelial cells without nuclear abnormalities**. Canti stressed that these **findings may be deceptive** and may conceal a melanoma in the deeper epithelial layers.

Merkel Cell Carcinoma (Primary Neuroendocrine Carcinoma of Skin)

Clinical Data and Histology

These uncommon neoplasms are highly malignant because of rapid vascular invasion and metastases, even when the primary lesions are only a few millimeters in diameter. These tumors, first described as **trabecular carcinomas of the skin** by Toker (1972), arise from neuroendocrine cells in the epidermis, known as **Merkel cells**, in elderly or immunosuppressed patients. Histologically, the tumors are composed of trabecular sheets or nodules of monotonous, small, cohesive epithelial tumor cells with finely granular chromatin and frequent mitotic figures (Fig. 34-12B). The **neuroendocrine differentiation** of these tumors can be documented by **ultrastructural studies** that revealed numerous membrane-bound, cytoplasmic, dense core granules, and by **cytochemistry** with chromogranin, neuron-specific enolase, and synaptophysin.

P.1297

Figure 34-12 Merkel cell tumor. *A.* High magnification of aspiration smears of a lesion of skin, stained for keratin to show the perinuclear deposits of intermediate filaments or intermediate filament buttons (red) in cells with scanty cytoplasm. *B.* Biopsy of the same lesion showing sheets of small tumor cells with foci of inflammatory cells. (Case courtesy of Prof. W. Domagala, Szczecin, Poland.)

Cytology

The tumor can be studied only in aspiration smears wherein the tumor cells are either **dispersed or form loosely structured clusters, sometimes forming rosettes** (Fig. 36-12A). The **cytoplasm** is scanty and disintegrates easily with resulting debris and naked nuclei. The **nuclei** are granular, but the **nucleoli** are either not visible or very small. The most characteristic feature of these tumors is the presence of **spherical, eosinophilic pink, cytoplasmic inclusions that are located near the nuclei or within nuclear indentations**, described as “**dot pattern**” by Collins et al (1998). The inclusions are composed of **intermediate keratin filaments (IF buttons)** and are best documented with antikeratin antibodies, such as cytokeratin 20 (Domagala et al, 1987). Even if the IF buttons cannot be demonstrated, a careful examination of the nuclei will disclose the presence of **indentations in the nuclear membrane** that may be diagnostically very helpful.

The **differential diagnosis** of Merkel cell carcinomas includes **metastatic oat cell carcinoma, metastatic carcinoids, malignant lymphomas, and occasionally other tumors such as melanomas composed of small cancer cells** and, very remotely, **basal cell carcinoma** that may be composed of cells of similar sizes. **Except for basal cell carcinoma that forms cohesive clusters of cells, all other tumors show dispersed cancer cells.** The differential diagnosis was very difficult prior to the discovery of the IF buttons (Pettinato et al, 1984). However, the presence of IF buttons is usually conclusive as a unique morphologic feature of Merkel cell carcinoma. It has also been proposed that Merkel cell carcinoma can be differentiated from other morphologically similar neoplasms by negative stain with **thyroid transcription factor 1** which identifies tumors of thyroid and bronchogenic origin (Cheuk et al, 2001; Leech et al, 2001).

Malignant Lymphomas

Primary malignant lymphomas of the skin are mainly **T-cell lymphomas**, known as **mycosis fungoides** and **Sézary's syndrome**. Also, the **CD30-positive, large cell lymphoma (Ki lymphoma)** often has cutaneous manifestations (Macgrogan et al, 1996). Recently, patients with **blastic natural killer cell** and other cytotoxic lymphomas have been described as a separate category (summary in Massone et al, 2004). The skin lesions have no specific histologic or cytologic features. Tani et al (1999) described the cytologic features of **plasma cell neoplasms**, several presenting as subcutaneous nodules. All these entities are discussed in Chapter 31.

Uncommon Primary Tumors of Skin and Adnexa

The repertoire of uncommon tumors of the skin and adnexa is large and of limited interest to the cytopathologist. Sporadic descriptions of unusual tumors of the skin and skin adnexa have appeared in the literature as case reports.

Thus, **lymphoepithelioma-like carcinoma** of the skin is similar in many ways to the carcinoma of the nasopharynx and possibly related to Epstein-Barr virus infection (Lind et al, 1999). The cytology of this tumor has been described by Chen (1999) as a **mixture of epithelial cancer cells and lymphocytes**, matching the findings in the nasopharynx (see Chap. 21).

Blandamura et al (1997) reported a case of metastatic **porocarcinoma**, a very uncommon tumor of sweat glands.

Tumors of soft tissues may mimic tumors of skin and adnexa. Tumors of nerves, mainly **schwannomas (neurilemmomas)** may occasionally occur in the skin (McMenamin and Fletcher, 2001). For description of cytology of these tumors, see Chap. 33). We have also observed a number of other malignant tumors of soft parts, masquerading as skin

P.1298

tumors. Among them were **myxoliposarcomas, rhabdosarcomas**, and single cases of **alveolar soft part sarcoma**, mimicking a metastatic carcinoma and **leiomyosarcoma**. These tumors are described and illustrated in Chapter 35.

Figure 34-13 Kaposi's sarcoma of palate. *A.* A small cluster of spindly cancer cells in a background of blood. *B.* Histologic section of the same tumor in subepithelial location. Note prominent vascular channels lined by cuboidal endothelial cells and surrounded by sheets of spindly fibroblasts. The latter are the cells seen in smears. (Case courtesy of Dr. Britt-Marie Ljung, San Francisco, CA.)

Kaposi's sarcomas occur in two forms: cutaneous and disseminated, the latter being endemic in parts of Africa (Antman and Chang, 2000). The tumors may be aspirated, particularly in patients with AIDS. The smears are bloody but may contain small clusters of **spindly cancer cells** (Fig. 34-13). The rare cutaneous **epithelioid angiosarcomas** may mimic a metastatic carcinoma because of large size of cancer cells (Abele and Miller, 1982; Fletcher et al, 1991; Ng et al, 1997; Minimo et al, 2002).

METASTATIC TUMORS

From time to time, skin and subcutaneous tissue metastases may occur with almost any primary cancer (Koss et al, 1992; Reyes et al, 1993; David et al, 1998; Gupta and Naran, 1999). Perhaps the most frequent use of aspiration biopsy on cutaneous lesions, however, is in the diagnosis of **recurrent mammary carcinoma in mastectomy scars** (Fig. 34-14). In this setting, the main differential diagnosis is among **scar keloid, stitch abscess, inclusion cyst,**

subcutaneous endometriosis (discussed above), and cutaneous metastasis. The dispersed malignant cells are readily recognized (see Chap. 29). In difficult cases, a **comparison with the previous aspiration or surgical biopsy is advisable.** Among many other metastatic tumors of various origins, we observed an exceptional case of a **neuroblastoma** in an 18-month-old boy. The small cancer cells formed **conspicuous rosettes** (Fig. 34-15A) that were shown to contain slender neurofilaments (Fig. 34-15B).

Figure 34-14 Metastatic mammary carcinoma in mastectomy scar. Small, dispersed cancer cells with scanty cytoplasm and nuclei of variable sizes, comparable to the lobular carcinoma that was previously excised.

Sister Mary Joseph's Nodule

Sister Mary Joseph, working at the Mayo Clinic at the turn of the 20th century, observed that **nodules in the area of the umbilicus may represent metastatic cancer** (excellent summary in Schneider and Smyczek, 1990). The most important source of these metastases is **ovarian cancer** but other intraabdominal cancers may cause the lesion. In our small series, cancers of the **colon, pancreas and lung** were represented (Fig. 34-16) (Hoda et al, 1997). Grunewald et al (1996) described a case of a malignant **carcinoid tumor** with umbilical metastasis. Cytologic recognition of cancer cells in the aspirate is easy. Lopez and Rodil (1998) reported that **benign umbilical cysts** can mimic Sister Mary Joseph's nodule.

Soft Tissue Lesions

Bogdan Czerniak

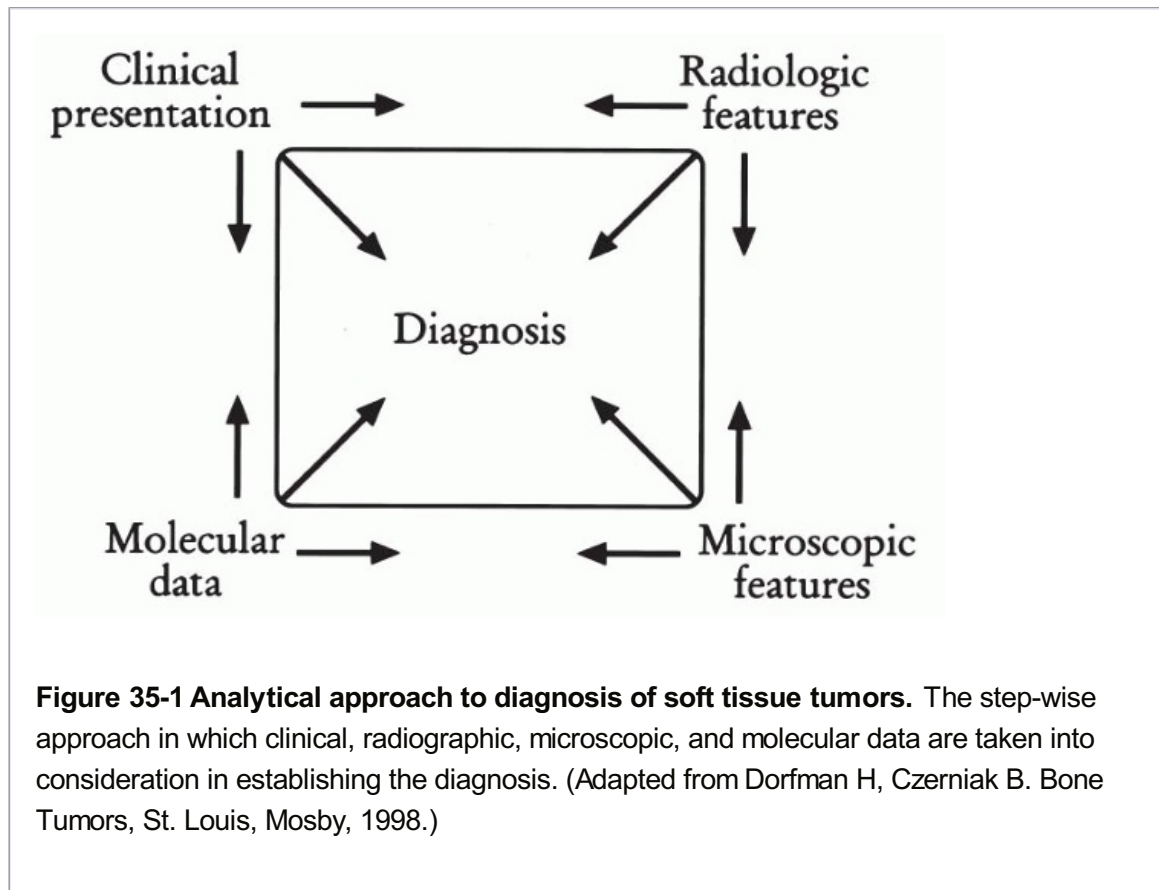

Tomasz Tuziak

Soft tissue tumors and tumor-like conditions, a highly heterogeneous group of lesions, are classified on the basis of their overall microscopic appearance, tissue differentiation pattern, clinical presentation, and biologic potential. In general, they are classified into several major histogenetic categories according to their exclusive or dominant lineage differentiation pattern. Within each major histogenetic category, the lesions are further separated into benign and malignant tumors. **Benign tumors** have limited local growth potential. They typically grow in a noninvasive expansile fashion and in the vast majority of cases can be eradicated by conservative excision. In contrast, **malignant soft tissue tumors or sarcomas** are at least locally aggressive and grow in an invasive, destructive fashion. Clinical behavior of these tumors is characterized by continuous growth with multiple local recurrences and, sometimes, distant metastasis. The clinical aggressiveness varies among different categories of malignant tumors and even among individual tumors of the same class. As a group, sarcomas are characterized by a relatively high incidence of distant blood-borne metastases primarily to the lungs, but some of them may initially metastasize to regional lymph nodes.

Soft-tissue sarcomas are less common than epithelial malignancies and constitute less than 1% of human cancers. Over the 15-year period of 1973-1987, 19,684 sarcomas were reported to the National Cancer Institute's Surveillance Epidemiology and End Results Program, and more than half of them (10,034 cases) arose in soft tissue. The incidence rates calculated on the basis of these data show gradual increases in relation to age. The overall age-adjusted incidence rate is 2.4 and 1.6 per 100,000-individuals for males and females respectively. Malignant fibrous histiocytoma (20% of all soft tissue sarcomas) is the most frequently diagnosed sarcoma followed by liposarcoma (18.3%), leiomyosarcoma (8.8%), fibrosarcoma (8.0%), rhabdomyosarcoma (6.7%), Kaposi's sarcoma (3.4%), synovial sarcoma (3.9%), and malignant peripheral nerve sheath tumor (3.6%). Median age at diagnosis for all soft tissue sarcomas is 54.8 years for males and 55.3 years for females.

The clinical course of sarcomas varies not only among tumors of different types but also among individual lesions of the same type. Therefore, in addition to histologic type, such information as grade and stage are important in assessing prognosis. The original grading system proposed by Broders (1922, 1939) was based on microscopic features such as (1) cellularity, (2) pleomorphism, (3) mitotic activity, (4) necrosis, (5) type of growth (expansive versus invasive). In reference to sarcomas two of their microscopic features, i.e., the frequency of **mitotic figures** and the **extent of necrosis**, are the most important parameters for **histologic grading**. The most frequently used three-tier system separates tumors into a well-differentiated category (grade 1) and a poorly differentiated category (grade 3). The intermediate tumors

are classified as grade 2 lesions. The frequently used four-tier system shows minimal differences between the two lower grades (grades 1 and 2) and two higher grades (grades 3 and 4). **For practical use, the soft tissue sarcomas are frequently divided into two major categories, low and high grade.** The low-grade category typically signifies a predominantly locally aggressive tumor with minimal or no potential for metastases. The lesions designated as high-grade tumors typically have a high propensity for distant metastasis.

In this chapter we retain the conventional approach to the classification of soft tissue sarcomas, dividing them into several major histogenetic categories based on their overall microscopic appearance, tissue differentiation pattern, and biologic potential. We advocate a multimodal approach, graphically depicted as the so-called diagnostic quadrangle, which describes a step-wise analysis in which four distinctive data sets—clinical, radiographic, microscopic, and molecular—are considered to establish the diagnosis and treatment plan (Fig. 35-1). Such step-wise analysis is more likely to lead to consistency and accuracy than an intuitive approach based on fragmentary data.

BIOPSY TECHNIQUES OF SOFT TISSUE LESIONS

Planning biopsies of soft tissue lesions is a complex procedure, as it must take into account the technical aspects of definitive surgery. Inappropriately performed biopsies can complicate subsequent surgery or even eliminate some treatment options. For example, an incorrectly placed biopsy incision may make optimal limb-sparing procedures impossible because of the danger of tumor seeding at planned excision margins. The ideal approach begins with preoperative consultations among the surgeon, medical oncologist, radiologist, and pathologist to understand the clinical setting and to establish the optimal diagnostic and therapeutic plan.

Frequently, **needle aspiration cytology**, under the guidance of radiographic imaging techniques, is used as a **preliminary diagnostic approach** that is particularly valuable when the lesion is not readily accessible to open biopsy. Unfortunately, in many instances, the aspirated samples do not provide sufficient material for final diagnosis. The lesions that are extremely difficult or even impossible to diagnose from limited material provided by fine needle aspirations or core needle biopsies require open incisional or excisional biopsy.

Cytological preparations such as touch smears, scrapes, or needle aspirations can assist in the intraoperative assessment of open biopsy material and can provide valuable information on the morphology of individual cells and the architecture of cell clusters not distorted by freezing artifacts. At the time of preliminary examination of material obtained by closed or open biopsy technique, a decision must be made as to whether the specimen requires some additional diagnostic procedures such as immunochemistry electron microscopy, cytogenetics, or other molecular analysis.

FUNDAMENTALS OF MOLECULAR BIOLOGY OF SOFT TISSUE TUMORS

During the last two decades our knowledge of the molecular events responsible for the development and progression of human tumors, including those that arise in the soft tissue, has dramatically increased because of numerous technological developments (Busam and Fletcher, 1997). The application of these techniques to the study of soft tissue tumors has led to a significant increase in new information about the molecular mechanisms responsible for malignant transformation of these rare, poorly understood neoplasms (Anderson et al, 1999; Argatoff et al, 1996).

The molecular regulation of mesenchymal cell differentiation is only superficially known. All of the five major lineages of mesenchymal origin (**chondroblastic, osteoblastic, lipoblastic, muscular, and fibroblastic**) originate from pluripotential mesenchymal cells. Some of the major master genes responsible for triggering lineage differentiation for pluripotential mesenchymal cells are shown in Figure 35-2. These genes trigger the activation of lineage-specific genes responsible for unique phenotypic change of responsive cells (Rodan and Harada, 1997). The myoD gene serves as a paradigm of such master regulators, causing expression of genes characteristic of the muscle phenotype.

Unique phenotypic features of distinct mesenchymal lineages and their tumors aid in the classification of soft tissue neoplasms. Unfortunately, the tumors that originate from individual lineages do not always exhibit the same phenotype. A good example of such an abnormal phenotype is a rare expression of cytokeratins in Ewing's sarcoma/PNET or characteristic coexpression of desmin and cytokeratins in small cell desmoplastic tumor. Therefore, the classification of the tumor on the basis of its phenotypic features by immunohistochemistry is complex and requires knowledge not only of normal phenotype of each individual mesenchymal lineage but also of a large array of aberrant features found in individual tumor types. The purpose of this summary

P.1304

is to present the **diagnostic impact of various molecular features on the differential diagnosis of soft tissue tumors.**

Many soft tissue sarcomas exhibit pronounced aneuploidy with alterations of multiple chromosomes. However, in contrast to more common epithelial neoplasms, the **soft tissue tumors have a high incidence of specific chromosomal translocations** associated with formation of novel tumor-specific chimeric genes (Fletcher et al, 1991a; May et al, 1993; Sandberg and Bridge, 1994; Sreekantaiah et al, 1994;

P.1305

Ladanyi, 1995). The specificity of these translocations and their gene products is becoming an integral part of the diagnostic work-up of some soft tissue neoplasms. These features are especially helpful in cases that are histologically, pathologically, and clinically equivocal (Ladanyi and Gerals, 1994; Panagopoulos et al, 2002; Sandberg and Bridge, 2002). Diagnostically valid chromosomal translocations and their associated chimeric genes are summarized in Table 35-1. More detailed discussion of these translocations is provided under sections devoted to specific tumors.

TABLE 35-1 CHROMOSOMAL TRANSLOCATION AND GENE REARRANGEMENTS IN SOFT TISSUE SARCOMAS		
Tumor Type	Cytogenetics	Genes Involved
EWS/PNET	t(11;22) (q24;q12)	FLI-1-EWS

	t(21;22) (q22;q12)	ERG-EWS
	t(7;22) (p22;q12)	ETV1-EWS
Desmoplastic small round cell tumor	t(11;22) (q13;q12)	WT1-EWS

Myxoid and round cell liposarcoma	t(12;16) (q13;p11)	CHOP-TLS
	t(12;22) (q13;q11)	CHOP-EWS
Synovial sarcoma	t(x;18) (p11;q11)	SSX1-SYT
		SSX2-SYT

Although chromosomal translocation and the resulting chimeric genes represent prototypic diagnostically valid molecular abnormalities found in soft tissue tumors, other less specific genetic changes, such as chromosomal deletions or gains, can also be diagnostically useful. A selected list of various genetic changes other than translocations found in some benign and malignant soft tissue tumors is provided in Table 35-2.

TABLE 35-2 CHROMOSOMAL ABNORMALITIES OTHER THAN TRANSLOCATION IN BENIGN AND MALIGNANT SOFT TISSUE TUMORS

Tumor type	Cytogenetic abnormality
Benign	
Benign schwannoma	Monosomy 22
	Trisomy 7
	Del of sex chromosome

Lipoblastoma	Rearrangement of 8q
Lipoma	
Ordinary	Rearrangements of 6p, 12q, 13q14-15
Intramuscular	Rearrangements of 8q, 12q
Spindle cell/pleomorphic	Rearrangements of 13q, 16q
Hibernoma	Rearrangements of 11q
Uterine leiomyoma	t(12;14) (q15;q24); del (7q); trisomy 12
	Trisomy 5, 7; t(1;2); t(1;14)
	Del (22q11.2)
Desmoid	Trisome 8 and/or 20
	Deletion of 5q
Schwannoma	Deletion of 22q
Malignant	
DFSP	Supernumerary ring chromosome (chr. 17, 22)
Infantile fibrosarcoma	
Leiomyosarcoma	+ 8, + 11, + 17, + 20 del (1p)
Well-differentiated liposarcoma (atypical lipoma)	Ring chromosome 12
Embryonal rhabdomyosarcoma	+ 2q, + 8, + 20; del 1
Mesothelioma	del (1p), del (3p), del (22q) + 1,
MPNST	Complex karyotypes, NF1 inactivation del (1p)

Neuroblastoma	Monosomies 14 and 22 del 1p
Gastrointestinal stromal tumor	
DFSP, dermatofibrosarcoma protuberans; MPNST, malignant peripheral nerve sheath tumor.	

FIBROUS AND FIBROHISTIOCYTIC LESIONS

The lesions of fibrohistiocytic tissue can be divided into three major groups: (1) **clinically benign proliferations** that typically do not recur after conservative local excision, (2) **ill-defined local proliferations** with high propensity for local recurrence but virtually no metastatic potential, (3) **aggressive, fully malignant tumors** with high propensity for distant metastasis.

Benign Lesions

Fibrous Histiocytoma

Pathology and Histology

Fibrous histiocytoma is a frequent, benign, slowly growing cutaneous lesion of adults with predilection for extremities (Gonzalez and Duarte, 1982; Fletcher, 1990). Less frequently

P.1306

it presents as a subcutaneous lesion without skin involvement. It is extremely rare in deep soft tissue, parenchymal organs, or bone (Meister et al, 1978b). The vast majority of lesions are not larger than 2 cm in diameter. They usually present as solitary flat skin lesions, but in 30% of the cases they are multifocal. Approximately 5% to 10% of the lesions recur after simple excision. Fibrous histiocytoma grows as a relatively well circumscribed nodule composed of a mixture of spindle and plump oval cells arranged in ill-defined fascicles forming a criss-cross pattern. Foamy histiocytic cells and hemosiderin deposits as well as multinucleated giant cells with peripheral nuclei of Touton type can be present. The lesion is typically separated from the overlying epidermis, but its deep aspects may show irregular infiltration of the subcutis.

Immunohistochemically fibrous histiocytomas express factor XIIIa and tinascin, which suggest that these tumors arise from dermal dendrocytes (Reid et al, 1986; Cerio et al, 1990). Lack of CD34 expression is helpful in distinguishing fibrous histiocytoma from dermatofibrosarcoma protuberans, which is consistently positive for this marker (Kamino and Salcedo, 1999).

Cytology

Aspirates from fibrous histiocytoma are cellular and contain multiple **clusters of tightly packed cells**. They represent a mixture of **plump spindle, oval, or polygonal cells** with vesicular nuclei and small inconspicuous nucleoli. Rare multinucleated giant cells corresponding to Touton cells and foamy macrophages can be also found. Usually there is an admixture of inflammatory cells such as lymphocytes and plasma cells.

Fibromatoses

Pathology and Histology

Fibromatoses comprise a wide spectrum of borderline fibrous tissue lesions involving various anatomic sites (Stout, 1961; Allen, 1977). The unifying theme is a multinodular diffuse proliferation of well-differentiated fibrous tissue with high propensity for local recurrence but virtually no metastatic potential (Fig. 35-3A,B). According to their anatomic location, **fibromatoses** are divided into two major groups: **superficial and deep** (Burke et al, 1990). Palmar fibromatosis is by far the most frequent superficial form of fibromatosis. Originally described by Dupuytren, it is still referred to as **Dupuytren's contracture** (Gabbiani and Majno, 1972). Other typical sites of involvement by superficial fibromatoses are the hand (palmar fibromatosis), foot (plantar fibromatosis), and penis (penile fibromatosis). Congenital fibromatoses and fibromatoses of infancy often affect the head and neck area.

Deep soft tissue musculo-aponeurotic fibromatoses have predilection for the shoulder, chest wall, and thigh (Enzinger and Shiraki, 1967). **Desmoid tumor** involving the abdominal muscular structures of young women during or following pregnancy is a prototypic fibromatosis related to trauma (Karakousis et al, 1993). A distinct group of intraabdominal mesenteric fibromatoses is associated with Gardner's syndrome (Naylor et al, 1979). Idiopathic retroperitoneal fibrosis is discussed in Chapter 40.

Cells of fibromatosis express vimentin, and different muscle markers such as smooth muscle actin, muscle-specific actin, and desmin. Expression of these markers is variable and depends on the degree of myofibroblastic differentiation. Expression of CD117 (c-kit), originally considered to be characteristic of gastrointestinal stromal tumor (GIST), is present in nearly 75% of the cases. In contrast to GIST, fibromatoses are consistently negative for CD34 (see Chap. 24).

Cytology

Superficial fibromatoses are practically never diagnosed by cytology. Fine-needle aspirations of deep lesions are performed in order to rule out high-grade sarcomas. The aspirates contain large, three-dimensional fragments of fibrous tissue and sparse isolated fibroblast-like spindle cells (Sauer et al, 1997; Pereira et al, 1999; Kurtycz et al, 2000). There is no cytologic atypia or mitotic activity (Fig. 35-3C-E) (Liu et al, 1999a).

Malignant Lesions

Dermatofibrosarcoma Protuberans

Pathology and Histology

Dermatofibrosarcoma protuberans, a tumor of intermediate grade of malignancy, typically presents as a cutaneous mass with predilection for the trunk and proximal portions of the extremities (Fletcher et al, 1985). It primarily affects individuals during their early or middle adult life. Early lesions present as flat indurations of the skin, enlarging to produce a multinodular, protruding mass (Burkhardt et al, 1966). The tumor is a locally aggressive lesion with **high propensity for local recurrence** (approximately 50%) and only minimal metastatic potential (Burla and Gotz, 1965; Connelly and Evans, 1992; Mentzel et al, 1998). Microscopically it is composed of **densely packed short spindle cells** arranged in a distinct **storiform pattern** that show only minimal nuclear atypia. Tumor diffusely infiltrates the dermis and subcutis, creating a very characteristic lace-like pattern at its periphery (Fig. 35-4A,B). In rare instances dermatofibrosarcoma protuberans can **progress to a low-grade or even high-grade fibrosarcoma** with malignant fibrous histiocytoma-like features (Mentzel et al, 1998).

Surprisingly, several recent studies indicate that this progression does not significantly increase the local recurrence rate or metastatic potential.

Immunohistochemically, dermatofibrosarcoma is characterized by expression of CD34, suggesting its origin from CD34-positive dermal dendritic cells (Goldblum and Tuthill, 1997) Cytogenetically, dermatofibrosarcoma protuberans is characterized by supernumerary chromosomes consisting of amplified sequences from chromosomes 17 and 22. Fusion of the PDGF β -chain gene with COL1A1 (collagen 1 α 1 gene) puts the PDGF β gene under control of the COL1A1 promoter, creating a novel fusion protein.

P.1307

Figure 35-3 Fibromatosis. *A,B.* Histologic appearance of fibromatosis. Note uniform proliferation of fibroblastic cells showing no atypia and only minimal mitotic activity. *C-E.* Cytologic features of fibromatosis. Note isolated spindly fibroblastic cells with indistinct cytoplasm. Benign looking nuclei with evenly distributed chromatin show neither hyperchromasia nor nucleoli.

Cytology

Cytologic preparations from dermatofibrosarcoma protuberans are highly cellular and consist mostly of **large 3-dimensional aggregates of densely packed short spindle cells** with plump ovoid nuclei and scant cytoplasm (Fig. 35-4C). Atypia is minimal and the nuclei contain evenly distributed chromatin with small, inconspicuous nucleoli (Filipowicz et al, 1999). Large cellular aggregates may contain prominent, branching capillary vessels surrounded by tightly packed tumor cells (Fig. 35-4D).

Fibrosarcoma

Pathology and Histology

The most significant difference between fibromatosis and fibrosarcoma is that the latter is capable of metastases (Stout, 1954; Oshiro et al, 1994). Fibrosarcoma is most frequent between ages 30 and 50 years and is predominantly found in deep soft tissue of the lower extremities (Scott et al, 1989). The characteristic microscopic feature is **uniform growth of fibroblastic spindle cells** with scanty cytoplasm separated by collagen deposits forming intersecting bundles reminiscent of herringbone (Fig. 35-5A,B). Tumors with admixture of inflammatory cells (**inflammatory fibrosarcoma**), tumors with stromal sclerosis and epithelioid change (**sclerosing epithelioid sarcoma**), and stromal myxoid change (**low-grade fibromyxoid sarcoma**) represent distinct clinicopathologic forms of fibrosarcoma (Evans, 1987; Meis-Kindblom et al, 1995; Dvornik et al, 1997; Eyden et al, 1998). Fibrosarcoma may also affect newborns and infants (**congenital or infantile fibrosarcoma**), in these cases typically arising in the extremities. Histologically they are similar to adult fibrosarcoma but are less aggressive (Schofield et al, 1994).

P.1308

Figure 35-4 Dermatofibrosarcoma protuberans (DFSP). *A,B.* Histologic appearance of dermatofibrosarcoma protuberans. Neoplastic cells showing minimal atypia are arranged in storiform pattern. Note infiltration of tumor cells among adipocytes of subcutaneous fat. *C,D.* Cytologic features of dermatofibrosarcoma protuberans. Note large, 3-dimensional tissue fragments with discernable storiform pattern. The cells have scanty basophilic, elongated cytoplasm. The nuclei show evenly distributed chromatin and only small, inconspicuous nucleoli. Accumulations of cells around capillary vessels can be seen.

P.1309

Immunohistochemically, fibrosarcoma express vimentin and may show scattered positivity for muscle markers (smooth muscle or muscle-specific actin) consistent with myofibroblastic differentiation. Negativity for epithelial markers is very useful in differential diagnosis with monophasic synovial sarcoma. Some special variants of fibrosarcoma such as sclerosing epithelioid type may, however, express epithelial membrane antigen and some neural markers including S-100 protein and neuron-specific enolase.

Cytology

Aspirations from fibrosarcoma are highly cellular and consist of loose **clusters of spindle cells** as well as many isolated single cells with elongated scanty cytoplasm and plump oval nuclei. The atypia is low to moderate, and the **nuclei contain evenly distributed chromatin and small nucleoli** (Fig. 35-5C,D). A fascicular arrangement of spindle cells is occasionally seen in larger clusters (Logrono et al, 1999a). Overall, **cytologic features overlap those of other spindle cell tumors** such as leiomyosarcoma, synovial sarcoma, and peripheral nerve sheath tumor (Liu et al, 1999b).

Malignant Fibrous Histiocytoma

Pathology and Histology

Malignant fibrous histiocytoma represents the most common soft tissue sarcoma of late adult life (Bertoni et al, 1985; Rooser et al, 1991; Fletcher, 1992). Tumors that belong to this category manifest a wide range of histologic appearances and can be subclassified into **storiform-pleomorphic, myxoid, giant cell, and inflammatory subtypes** (Weiss and Enzinger, 1978; Enzinger, 1986; Khalidi et al, 1997). The most frequent, the storiform-pleomorphic type, is characterized by a mixture of highly atypical spindle and pleomorphic cells arranged focally in a storiform pattern. There is usually an admixture of haphazardly scattered, highly atypical, multinucleated giant cells. Brisk mitotic activity with numerous atypical mitoses as well as areas of necrosis complement an overall highly malignant microscopic appearance of the tumor (Fig. 35-6A,B). Myxoid subtype is the second most frequent variant of malignant fibrous histiocytoma, characterized by prominent myxoid change in the stroma (Fig. 35-7A,B) (Weiss and Enzinger, 1977; Mentzel et al, 1996). Tumors with a diffuse prominent myxoid change behave less aggressively than do other types of malignant fibrous histiocytoma. Giant cell variant contains numerous osteoclast-like giant cells, while a significant admixture of inflammatory cells is seen in a subset of these tumors referred to as **inflammatory malignant fibrous histiocytomas** (Khalidi et al, 1997).

Immunohistochemistry has limited application in diagnosis of malignant fibrous histiocytoma. The main role for special stains is to rule out specific lineage of differentiation such as epithelial, rhabdoid, or melanocytic.

Cytology

Aspirates from malignant fibrous histiocytoma are highly cellular and contain **obviously malignant, highly pleomorphic, cancer cells with eosinophilic cytoplasm** arranged in large sheets, and small clusters or as individual cells. The cells vary in size and shape. The nuclei of the tumor cells show pronounced atypia with irregular clumped chromatin granules and prominent nucleoli (Fig. 35-6C,D). **Multinucleated giant cells** as well as cells with bizarre nuclei are common. Cellular debris reflecting tumor necrosis and an admixture of inflammatory cells can be present. Tumor cells show brisk mitotic activity—atypical mitoses are easy to find (Berardo et al, 1997; Bosch-Princep et al, 2000).

The myxoid variant of malignant fibrous histiocytoma is characterized by less cellular smears and the presence of **pinkish myxoid material** in the background (Fig. 35-7C-E). A characteristic cytologic feature of this tumor is the presence of **curved capillary vessels** with attached neoplastic cells surrounded by a myxoid material (Kilpatrick and Ward, 1999).

LESIONS OF ADIPOSE TISSUE

There are two basic types of adipose tissue: (1) **white fat**, which is predominantly located in the subcutaneous tissue and retroperitoneum, and (2) **brown fat**, which is typically found in the interscapular and neck regions. White fat is a source of energy and functions as a mechanical protection for other tissues. Infants and children have a substantial amount of brown fat, but it undergoes involution with increasing age. **Adipocytes of white fat** are polygonal cells containing a **single large globule of fat that displaces the nucleus to the periphery of the cytoplasm**. The **cells of brown fat are smaller** and contain a **centrally located nucleus** with fat deposited within the cytoplasm in **multiple small droplets**. Lipoma and liposarcoma are the prototypic tumors of adipose tissue.

Cells of both benign and malignant fatty tumors stain for vimentin and S-100 protein. Since these markers are expressed in many different soft tissue tumors, they are of little help in the differential diagnosis of lipomatous lesions.

Lipoma

Pathology and Histology

Lipomas, which are almost exclusively found in adults, have a strong predilection for men (Brasfield and Das Gupta, 1969). They can be solitary or multiple and most frequently involve the subcutaneous adipose tissue. They are practically never seen in the face or scalp regions. Subcutaneous lipomas are well-circumscribed lesions. Less frequent, deeply located intermuscular lipomas show diffuse infiltration of skeletal muscles. Lipomas may show distinct microscopic features such as prominent vascular structure (**angiolipoma**), smooth muscle (**myolipoma**), a combination of smooth muscle and vessels (**angiomyolipoma**) (Belcher et al, 1974; Argenyi et al, 1991), a mixture of hematopoietic elements and adipose tissue (**myelolipoma**) (Chen et al, 1982), a chondroid appearance of adipose tissue (**chondroid lipoma**) (Meis and Enzinger, 1993), prominent multinucleated and spindle cells (**spindle cell lipoma, pleomorphic lipoma**) (Shmookler and Enzinger, 1981; Azzopardi et al, 1983; Fletcher and Martin-Bates, 1987; Digregorio et al, 1992), or immature adipose tissue (**lipoblastoma**) (Bolen and Thorning, 1984).

Smears are not as cellular as in pleomorphic storiform type, and cells show less atypia. Note myxoid material in the background. *Inset* shows group of tumor cells with distinct nucleoli.

P.1313

Ordinary lipomas exhibit three major types of cytogenetic abnormalities, involving rearrangements of the following chromosomal regions: (1) 12q14-15, (2) 6p21, and (3) 13q12-q14 (Sciot et al, 1997; Willen et al, 1998). The most frequently rearranged region, 12q14-15, involves a cluster of closely related genes coding for high-mobilitygroup (HMG) proteins. The three members of this superfamily (HMGIC, HMGI, and HMGIY) map to the 12q14-15 region and are frequently involved in translocations that result in overexpression of chimeric products of these genes (Fletcher et al, 1996).

Cytology

Aspiration cytology has little value in the diagnosis of superficial lipomas but may be helpful in elucidating the nature of tumors in unusual locations. Aspirations from conventional lipomas contain scanty cellular material consisting of **fragments of mature adipose tissue**, composed of mature adipocytes, described above.

Liposarcomas

Well-Differentiated Liposarcoma

Pathology and Histology

Well-differentiated liposarcoma is the most common form of liposarcoma in adults in their sixth to seventh decades of life. It is most frequently found in deep soft tissue of the extremities and retroperitoneum (Enzinger and Winslow, 1962; Bolen and Thorning, 1984). Well-differentiated liposarcomas, also referred to as **atypical lipomatous tumors** (Fig. 35-8A,B), are locally aggressive, nonmetastasizing lesions with a high propensity for local recurrence after excision (Evans, 1988; Weiss and Rao, 1992).

Well-differentiated liposarcomas are microscopically similar to benign lipomas. The distinguishing feature is the **presence of scattered cells with atypical hyperchromatic nuclei** (Evans, 1979). These cells have a tendency to cluster around fibrous septa. In a typical well-differentiated liposarcoma, these cells are easy to find, but occasionally such tumors may contain large areas of mature adipose tissue indistinguishable from lipoma. In such instances generous sampling of the tumor and careful microscopic evaluation are required to identify the few scattered atypical fat cells (Weiss, 1996).

Approximately 5% to 15% of well-differentiated liposarcomas lose their adipose tissue phenotype **after many local recurrences and progress to a high-grade sarcoma** with malignant fibrous histiocytoma-like features (Weiss and Rao, 1992). A dedifferentiated, high-grade sarcomatous component of the tumor may sometimes show a phenotypic switch to osteosarcoma, leiomyosarcoma, or even rhabdomyosarcoma (Salzano et al, 1991; Henricks et al, 1997).

Well-differentiated liposarcomas are characterized by supernumerary ring chromosomes containing amplified sequences derived from different chromosomes, particularly from chromosome 12 (Fletcher et al, 1996; Rosai et al, 1996). About 60% of well-differentiated liposarcomas contain giant ring chromosomes with amplified sequences of MDM2, SAS, GLI1, and HMCGI-C genes.

Cytology

Cytologic preparations of well differentiated liposarcoma are quite cellular and contain numerous oval fat cells that differ in size. **Lipoblastic cells with multivesicular cytoplasm and usually peripheral hyperchromatic nuclei containing prominent nucleoli** are typically present (Fig. 35-8C) (Nemanqani and Mourad, 1999; Wu et al, 1999). Scalloping of the nuclei by fat globules can be seen in some lipoblastic cells (Fig. 35-8D) (Dey, 2000). Extremely well-differentiated tumors can be cytologically indistinguishable from benign lipoma.

Myxoid and Round Cell Liposarcoma

Pathology and Histology

Microscopically, a **myxoid liposarcoma** is composed of primitive mesenchymal cells showing signs of early lipogenesis and a minor population of more mature lipoblastic cells loosely arranged in a **myxoid stroma** (Lai et al, 1991). The presence of a **network of curved plexiform capillary vessels** is a characteristic and diagnostically important feature of these tumors (Fig. 35-9A,B) (Bolen and Thorning, 1980). A **round cell liposarcoma** represents progression of myxoid liposarcoma and sometimes is referred to as its hypercellular variant (Kilpatrick et al, 1996a). It is characterized by the presence of densely packed primitive mesenchymal cells with a relatively minor population of lipoblastic cells. Areas of round cells are usually found in an otherwise typical myxoid liposarcoma. Tumors composed entirely of round cells are less frequent.

At the cytogenetic and molecular levels, myxoid and round cell liposarcomas are closely related and carry a unique (12:16) (q13;p11) reciprocal translocation resulting in the formation of a chimeric CHOP-TLS gene (Fig. 35-10A) (Knight et al, 1995; Kuroda et al, 1995; Tallini et al, 1996). In approximately 10% of cases an alternative (12; 22) (q13; q12) translocation involving CHOP and the 5' end of the EWS gene mapping to q12 region on chromosome 22 can be detected (Panagopoulos et al, 1996). CHOP is a transcription factor that belongs to the C/EBP family. Both CHOP and TLS-CHOP fusion proteins form dimers with C/EBP proteins. The TLS-CHOP and EWS-CHOP chimeric proteins function as potent transcription factors that deregulate the expression of a number of target genes (Fig. 35-10B) (Kuroda et al, 1995).

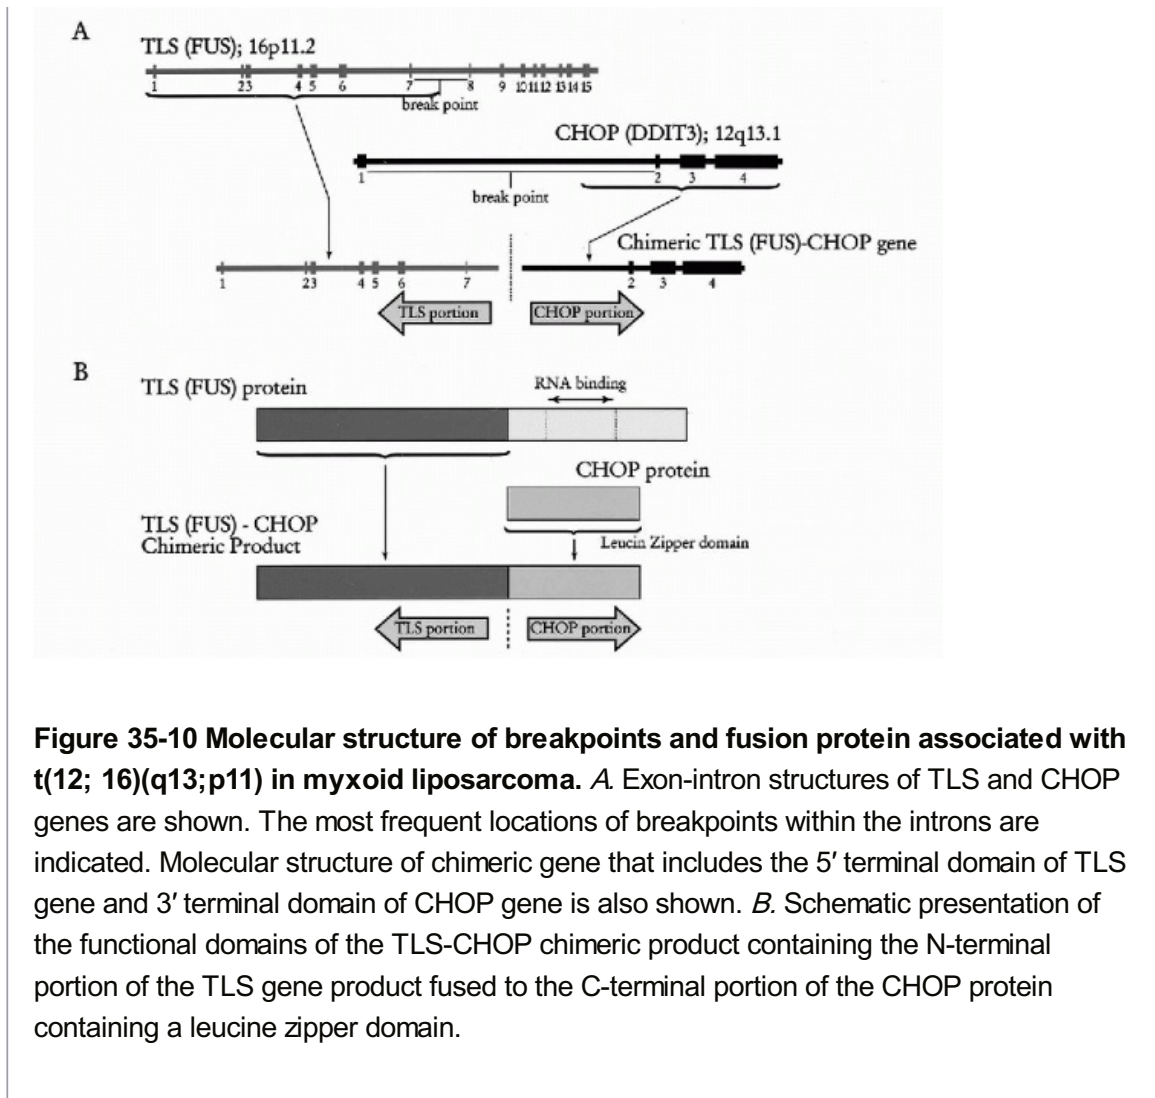

Figure 35-10 Molecular structure of breakpoints and fusion protein associated with t(12; 16)(q13;p11) in myxoid liposarcoma. *A.* Exon-intron structures of TLS and CHOP genes are shown. The most frequent locations of breakpoints within the introns are indicated. Molecular structure of chimeric gene that includes the 5' terminal domain of TLS gene and 3' terminal domain of CHOP gene is also shown. *B.* Schematic presentation of the functional domains of the TLS-CHOP chimeric product containing the N-terminal portion of the TLS gene product fused to the C-terminal portion of the CHOP protein containing a leucine zipper domain.

Cytology

The characteristic cytologic feature of myxoid liposarcoma is the presence of **curved branching capillary vessels** surrounded by irregular **lakes of myxoid material** that contain loosely arranged **primitive mesenchymal cells**, some of which may show **lipoblastic differentiation** (see Fig. 35-9C) (Attal et al, 1995). The cells have an overall bland cytologic appearance and resemble stellate, spindle, or rounded primitive mesenchymal cells with no or minimal lipoblastic features (see Fig. 35-9D) (Layfield et al, 1998). More mature cells with clearly recognizable lipoblastic differentiation are rare and may be difficult to find (Kilpatrick et al, 2000).

Pleomorphic Liposarcoma

Pathology and Histology

Pleomorphic liposarcoma is the least common, **highly malignant variant of liposarcoma** that accounts for only 10% to 15% of all malignant tumors of adipose tissue. Microscopically it is similar to malignant fibrous histiocytoma but the distinguishing feature is the presence of **large atypical cells with unequivocal lipoblastic differentiation** (Downes et al, 2001). Pleomorphic liposarcomas lack distinct cytogenetic alterations and exhibit complex chromosomal abnormalities with pronounced aneuploidy.

Cytology

Aspirates from pleomorphic liposarcoma are cellular and contain **highly atypical pleomorphic, obviously malignant cells**. As is the case for histologic sections, the overall cytologic appearance is **similar to that of malignant fibrous histiocytoma**. Cells with obvious lipoblastic features are difficult to identify in smears because the multivesicular cytoplasm of lipoblasts is frequently destroyed during aspiration and smear preparation.

LESIONS OF SMOOTH MUSCLE

The incidence of both benign and malignant smooth muscle tumors follows the distribution and volume of normal

P.1317

smooth muscles in the human body. Consequently they most frequently involve the genitourinary organs, predominantly the uterus, and the gastrointestinal tract (Wile and Evans, 1981; Gustafson et al, 1992). The smooth muscle tumors of soft tissue are extremely rare and are predominantly located in the retroperitoneum.

Leiomyosarcoma

Pathology and Histology

The rare retroperitoneal leiomyosarcomas primarily affect women 60-80 years of age (Wile and Evans, 1981; Shmookler and Lauer, 1983; Hashimoto et al, 1985). Microscopically, most leiomyosarcomas are composed of **spindle cells with obvious smooth muscle phenotype** exhibiting a mild to moderate degree of **nuclear atypia** arranged in intersecting fascicles (Fig. 35-11A,B). Prominent cytoplasmic vacuolization is a frequent feature (Fields and Helwig, 1981; Hashimoto et al, 1986). **Poorly differentiated lesions** show pronounced atypia and may have less obvious smooth muscle differentiation. Some leiomyosarcomas may show **epithelioid** and, less frequently, **clear cells** (Suster, 1994). Such features are usually seen focally in otherwise typical spindle cell leiomyosarcoma.

Immunohistochemically, leiomyosarcomas express the full range of muscle-specific markers. The most frequently detected are muscle-specific actin and desmin, which are positive in nearly 100% and 50% of cases, respectively. Typically there is an intense uniform staining for muscle-specific actin and less intense patchy staining with desmin.

Cytology

Uterine and cutaneous smooth muscle tumors are practically never diagnosed by cytology. Fine-needle aspirations are typically performed on deeply abdominal and soft tissue tumors (Fernando et al, 1998). Aspirates from leiomyosarcoma are usually highly cellular and contain numerous **spindle cells with cigar shaped blunt-ended nuclei** (Fig. 35-11C,D) (Hsu and Yang, 1995; Gupta et al, 2000). Occasionally a large **cytoplasmic vacuole** filling up a spindled cytoplasm and attached to the end of the nucleus can be seen (Ferretti et al, 1997). Similar to histologic sections, most leiomyosarcomas are cytologically well to moderately differentiated with minimal to moderate degree of nuclear atypia and obvious smooth muscle differentiation. High-grade lesions may show pronounced atypia with high mitotic activity and necrotic cellular debris. Such lesions may have less recognizable smooth muscle phenotype, and their overall cytologic appearance may **overlap with other high-grade spindle cell sarcomas** (Barbazzza et al, 1997; Palmer et al, 2001).

LESIONS OF SKELETAL MUSCLE

Rhabdomyosarcomas

Rhabdomyosarcoma represents the most common soft tissue sarcoma during **the first two decades** of life and primarily affects children under 15 years of age (Hollowood and Fletcher, 1994). It shows unique **anatomic predilection for the head and neck and genitourinary regions** and is less frequent in the extremities (Molenaar et al, 1985; Hawkins and Cancho-Velasquez, 1987). In addition, rhabdomyoblastic features can be seen in other tumors such as dedifferentiated chondrosarcoma, liposarcoma, or germ cell tumors. The composite tumors that exhibit **skeletal muscle and peripheral nerve differentiation are referred to as Triton tumors** (Daimaru et al, 1984). Rhabdomyosarcoma is also observed in mesodermal mixed tumors of the uterus, and as a component of tumors of childhood, such as Wilms' tumor (see Chap. 40 for discussion of these tumors). Based on distinct clinico-pathologic features, rhabdomyosarcoma can be divided into two main groups—pediatric (embryonal) and adult type. The pediatric embryonal rhabdomyosarcomas are subdivided into two prognostically and therapeutically important subgroups, alveolar and nonalveolar. The nonalveolar rhabdomyosarcomas are further descriptively designated as spindle, and round cell or botryoid variants (Cavazzana et al, 1992).

Embryonal Rhabdomyosarcoma

Pathology and Histology

Embryonal rhabdomyosarcoma is the **most frequent type of rhabdomyosarcoma affecting children** during the first decade of life, the mean age at presentation being about 7 years (Schmidt et al, 1986). Microscopically, the tumor is composed of varying proportions of primitive small blue round cells and spindle cells, which show features of rhabdomyoblastic differentiation comparable with myoblasts seen between 5 and 15 weeks of gestation (Fig. 35-12A,B). Cytoplasmic cross striations can be documented in about 50% of the cases, but they are difficult to find. Botryoid rhabdomyosarcoma is a variant of the embryonal type. It involves the mucosal membranes of the lower genitourinary tract and of other organs, where it grows as a **grape-like polypoid mass** (Hawkins and Cancho-Velasquez, 1987). Microscopically it is characterized by hypocellular areas with myxoid stroma containing sparsely distributed primitive mesenchymal cells showing early signs of rhabdomyoblastic differentiation (Matsuura et al, 1999). The peripheral subepithelial area of the tumor may show increased cellularity and is referred to as the cambium layer. The previously hopeless prognosis of this tumor has been significantly improved with contemporary treatment regimens of chemo- and radiotherapy (see also Chaps. 14 and 23).

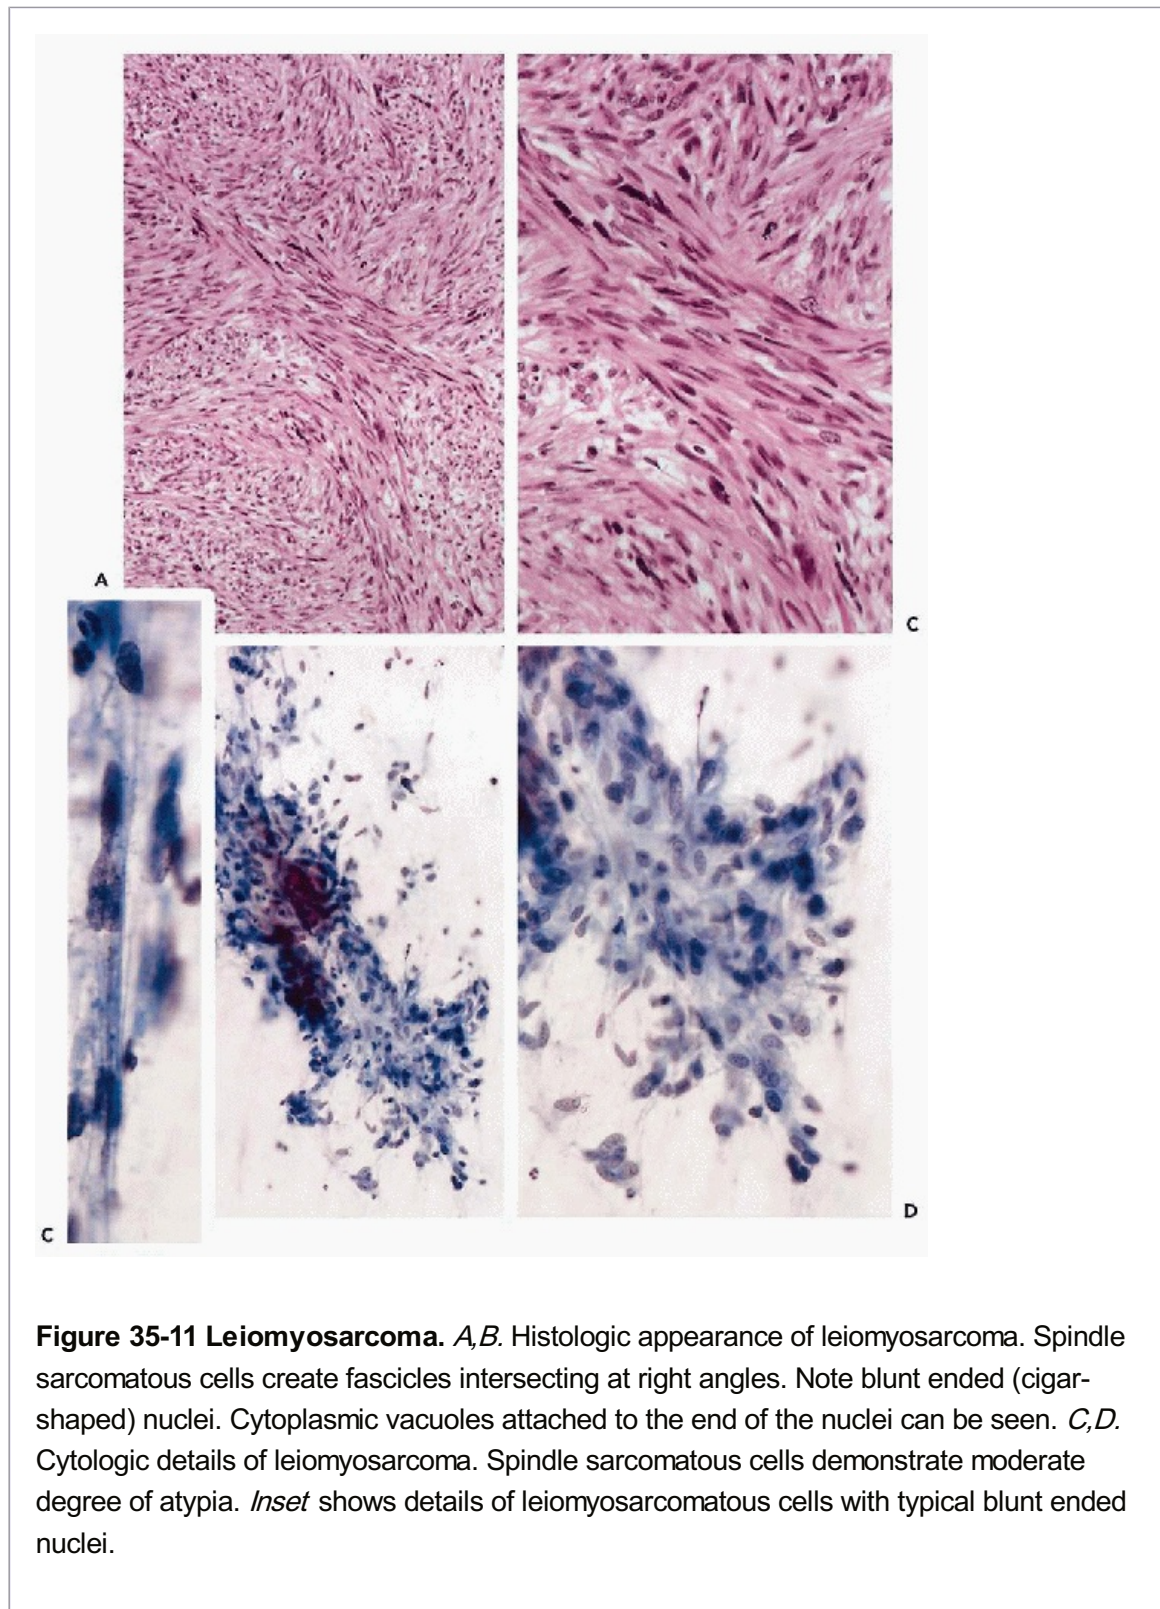

Cytology

Aspirates from embryonal rhabdomyosarcomas are usually highly cellular. Most frequently, they contain primitive round cells and occasionally, larger rhabdomyoblastic cells with oval or spindle eosinophilic cytoplasm (Agarwal et al, 1996; Atahan et al, 1998). The cytologic appearance varies among tumors and parallels the overall skeletal muscle lineage differentiation (Cohen et al, 1999). Better differentiated tumors may contain numerous large oval or spindle rhabdomyoblastic

P.1318

cells, some with cytoplasmic cross-striations. In such tumors multinucleated cells with strap-shaped cytoplasm reflecting myotubule differentiation can occasionally be found (Fig. 35-

12C,D) (Pohar-Marinsek and Bracko, 2000).

Alveolar Rhabdomyosarcoma

Pathology and Histology

Alveolar rhabdomyosarcoma is a rare distinct variant of pediatric rhabdomyosarcoma composed of **large primitive round cells forming alveolar structures** or, less frequently,

growing in solid nests of cells that do not adhere to each other (solid variant) (Fig. 35-13A,B) (Enzinger and Shiraki, 1969). The tumor exhibits the unique chromosomal translocations (2;13)(q35;q14) or (1;13)(p36;q14). The translocations result in formation of the two chimeric genes, PAX3-FKHR and PAX7-FKHR (Fig. 35-14A) (Weber-Hall et al, 1996; Anderson et al, 1997). The fusion proteins contain PAX3/PAX7 DNA binding domains and FKHR transcription activation domain (Fig. 35-14B) (Merlino and Helman, 1999). The chimeras activate transcription with higher potency than the corresponding wild-type PAX proteins and are insensitive to the ordinarily inhibitory effects

P.1320

of N-terminal PAX3 and PAX7 domains (Arden et al, 1996; Bennicelli et al, 1996). It is assumed that the PAX3-FKHR and PAX7-FKHR chimeric genes contribute to tumorigenic behavior by altering growth control, apoptosis, differentiation, and cell motility.

Figure 35-12 Embryonal rhabdomyosarcoma. A,B. Histologic appearance of embryonal rhabdomyosarcoma. Note spindle cells with deeply eosinophilic cytoplasm. C,D. Cytologic features of embryonal rhabdomyosarcoma. Note large 3-dimensional clusters of spindle

cells. Sarcomatous cells show only a wisp of cytoplasm, the rhabdomyoblastic differentiation is not always evident.

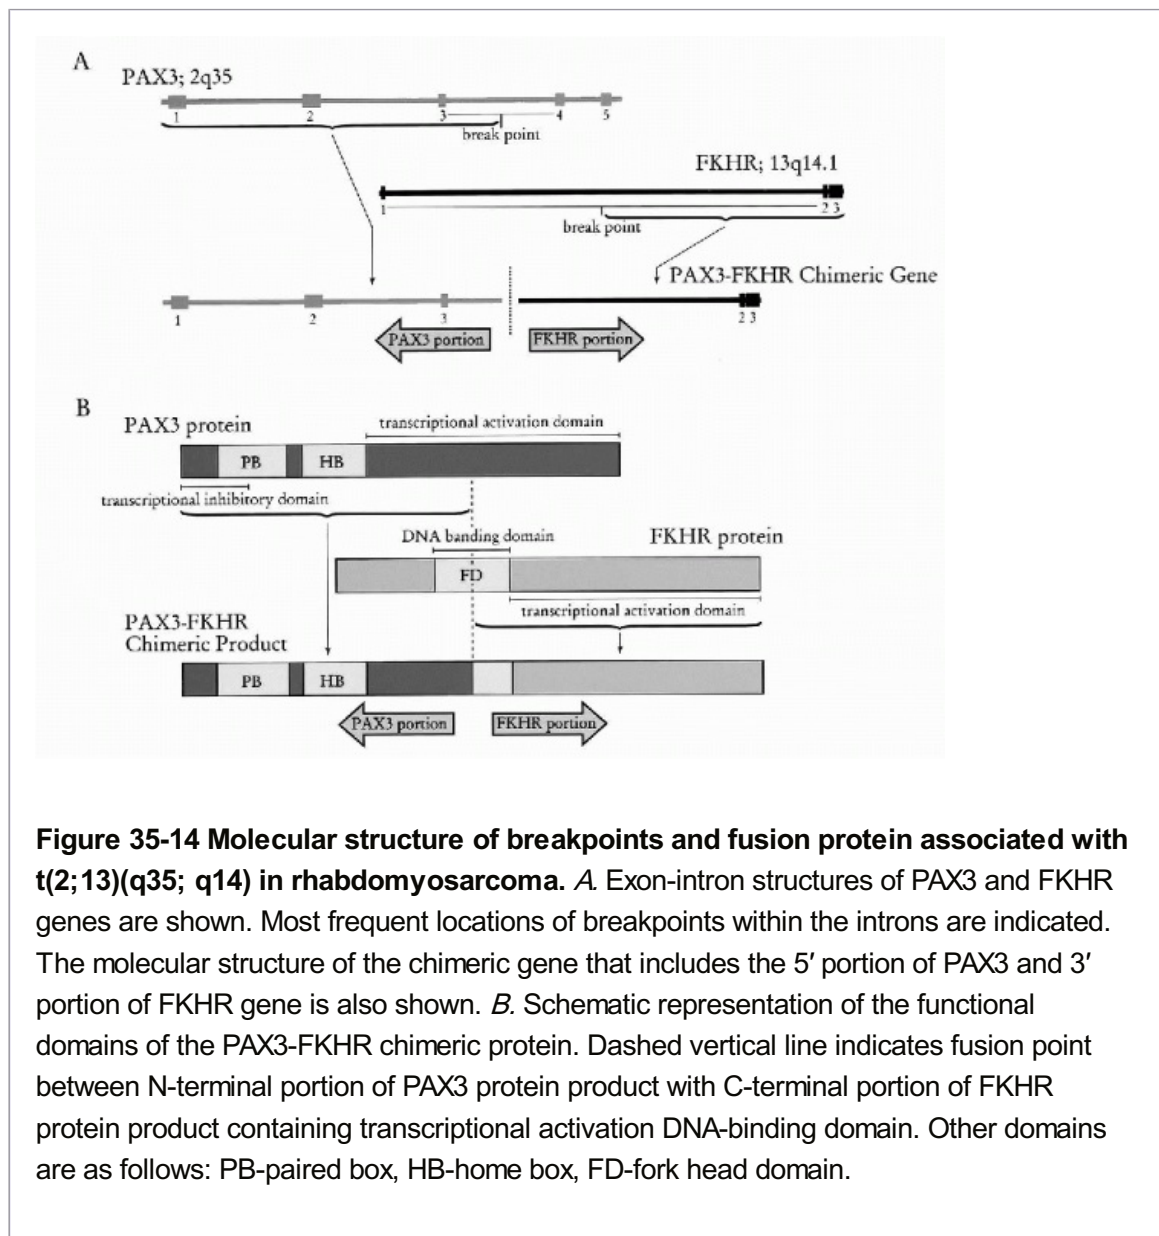

Figure 35-13 Alveolar rhabdomyosarcoma. *A,B.* Histologic appearance of alveolar rhabdomyosarcoma. Note alveolar arrangement of tumor cells. *C,D.* Cytologic features of rhabdomyoblasts with deeply staining cytoplasm. *Inset (left)* shows rhabdomyoblasts with large nucleoli. *Inset (right)* shows positive immunohistochemical staining for desmin in tumor cells.

Cytology

Aspirations from alveolar rhabdomyosarcoma are highly cellular and contain a monomorphic population of primitive oval rhabdomyoblastic cancer cells with occasional larger multinucleated cells (Suvana et al, 1998). The feature distinguishing

them from conventional small cell rhabdomyosarcoma is the larger size of rhabdomyoblastic cells, which contain a central nucleus with prominent nucleolus (see Fig. 35-13C,D).

Pleomorphic Rhabdomyosarcoma

Pathology and Histology

Pleomorphic rhabdomyosarcoma is the least frequent form of rhabdomyosarcoma, which typically involves the extremities of adults (Gaffney et al, 1993). It is composed of large **bizarre rhabdomyoblastic cells with dense eosinophilic cytoplasm and occasional cross striations**. The overall microscopic picture is similar to storiform-pleomorphic malignant fibrous histiocytoma (deJogn et al, 1987; Gaffney et al, 1993).

Cytology

Cytologic preparations from pleomorphic rhabdomyosarcoma contain numerous highly atypical rhabdomyoblastic cells of various shapes with **dense eosinophilic oval or polygonal cytoplasm**. Cytoplasmic cross-striations may be observed. As is the case with histologic sections, the overall cytologic picture is similar to storiform-pleomorphic malignant fibrous

histiocytoma. The distinguishing feature is the presence of cells with unequivocal rhabdomyoblastic features (Atahan et al, 1998).

LESIONS OF VASCULAR TISSUE

Vascular tumors consist of a wide spectrum of lesions ranging from benign to highly aggressive malignant neoplasms. **Benign vascular lesions** closely resemble normal vessels, and their distinction from vascular malformations and hamartomas is not always clear (Rao and Weiss, 1992). The vascular tumors that behave in an intermediate fashion between hemangiomas and angiosarcomas are referred to as hemangioendotheliomas (Weiss et al, 1986). This group consists of **epithelioid hemangioendothelioma, spindle**

P.1322

cell hemangioendothelioma, Kaposiform hemangioendothelioma, and the very rare **Dabska tumor** (Dabska, 1969; Fletcher et al, 1991b; Lai et al, 1991; Tsang and Chang, 1991; Ding et al, 1992; Pohar-Marinek and Bracko, 2000). These tumors typically show multifocal, locally destructive growth with high recurrence rate and minimal metastatic potential. Angiosarcomas represent a wide spectrum of organ-specific entities, and their complete description is beyond the scope of this text, which is limited to skin and accessible soft tissue lesions.

Hemangioma

Pathology and Histology

Hemangioma, one of the most common benign soft tissue tumors, is composed of an architecturally abnormal network of vessels (Allen and Enzinger, 1972; Nichols et al, 1992). Microscopically they can be separated into two major categories: (1) lesions composed of small capillaries (**capillary hemangioma**), and (2) those composed of larger, open vessels (**cavernous hemangioma**). Capillary hemangioma is most frequent during infancy and childhood and usually affects skin or subcutaneous tissue of the head and neck region. Characteristically it regresses with age in about 90% of the cases. Grossly, capillary hemangiomas represent an elevated red to purple skin lesions without ulcerations. Microscopically they are composed of capillary-sized vessels arranged in multilobular pattern. Cavernous hemangiomas tend to be larger and less well circumscribed than capillary hemangiomas. They more frequently involve deep soft tissue and internal organs and do not regress but may become fibrosed or calcified. **Intramuscular hemangioma** is a special type of hemangioma; most lesions appear in patients younger than 30 years of age and have a predilection for the lower extremities (particularly muscle of the thigh) (Beham and Fletcher, 1991). Microscopically, these hemangiomas are composed either of capillary or cavernous vessels. Because of its intramuscular localization and infiltrative pattern of growth, this tumor could be confused microscopically with angiosarcoma.

Cytology

Aspirates from hemangiomas are very infrequent. The smears are nearly acellular and contain sparse groups of small spindle cells admixed with peripheral blood.

Kaposi's Sarcoma

Pathology and Histology

There are four distinct clinical forms of Kaposi's sarcoma: (1) **chronic** (not associated with

acquired immunodeficiency syndrome), (2) **lymphadenopathic**, (3) **associated with transplantation**, and (4) **associated with acquired immunodeficiency syndrome (AIDS)**. Their detailed description is beyond the scope of this review (Ramos et al, 1976; Harwood et al, 1979; Chor and Santa Cruz, 1992). Most Kaposi's sarcomas in AIDS are associated with herpesvirus type 8 (Chang et al, 1994; Cesarman et al, 1995; Moore et al, 1996). The virus is located in the endothelial and spindle cells of the tumor (Boshoff et al, 1995). Ablashi et al (2002) reviewed the possible role that this virus may play in the genesis of this and other malignant tumors in AIDS (see also Chap. 26).

In general, Kaposi's sarcoma most frequently presents as **multiple purple skin nodules** slowly increasing in size and number. Microscopically, three steps of development can be distinguished: patchy, plaque, and nodular. The **earliest, microscopically recognizable phase consists of a proliferation of bland-looking small vessels** that gradually become confluent and finally **form an ill-defined nodule** composed of **spindle cells separated by slit-like spaces**, which may contain erythrocytes. Hyaline globules representing degenerated erythrocytes, hemosiderin deposits, and scattered inflammatory lymphocytes are usually present (Fukunaga and Silverberg, 1991). The clinical course is that of gradually progressing multifocal skin disease, which can also involve mucosal membranes, lymph nodes, and eventually internal organs. The prognosis is related to associated conditions such as AIDS.

Cytology

Aspirates from Kaposi's sarcoma are usually bloody or sparsely cellular and contain **small groups of spindle cells with very slender cytoplasm**. These cells contain elongated nuclei with evenly distributed chromatin. Overall cytologic features are similar to other low-grade spindle cell lesions (al-Rikabi et al, 1998). Aspiration cytology, however, is particularly helpful in evaluation of lymphadenopathy for primary Kaposi's tumors in patients known to have acquired immunodeficiency syndrome.

Angiosarcoma

Pathology and Histology

Angiosarcoma is one of the rarest soft tissue sarcomas, comprising less than 1% of all sarcomas. Chronic lymphedema, radiation therapy, and carcinogens such as thorium dioxide (Thorotrast), insecticides, and vinyl chloride have been recognized as etiologic factors. This description is limited to skin and soft tissue angiosarcomas only (Maddox and Evans, 1981). **Cutaneous angiosarcoma** can occur in two distinct clinical settings: (1) **not associated with lymphedema**, (2) **associated with lymphedema**. Cutaneous angiosarcoma not associated with lymphedema occurs in the elderly in the head and neck region and usually is well to moderately differentiated (Hodgkinson et al, 1979). Angiosarcoma associated with lymphedema most frequently develops in the skin of the upper extremity in women 8 to 10 years after mastectomy and radiotherapy for breast cancer (**Stewart-Treves syndrome**) (Martin et al, 1984; Ryan et al, 1998). Angiosarcoma of deep soft tissue occurs at any age and has a propensity for the extremities and abdominal cavity. **Postradiation angiosarcoma** most commonly involves the skin in the region radiated after breast sparing procedures for carcinoma.

Microscopically, angiosarcomas range from **well-differentiated lesions to highly anaplastic tumors** whose endothelial origin may be difficult to document without special studies such as electron microscopy or immunohistochemistry (Fletcher et al, 1991a). Vascular channels

creating anastomosing network and sinusoids which dissect preexisting collagen and fat tissue are characteristic of well-differentiated

P.1323

tumors. These **channels are lined by plump endothelial cells with hyperchromatic nuclei** exhibiting only minimal atypia. In **moderately differentiated tumors**, the atypia is more obvious, and focal proliferation of endothelial cells with piling up and creation of intraluminal papillary tufts is present (Fig. 35-15A,B). The **poorly differentiated tumors** are characterized by the presence of a solid **spindle or epithelioid cell components** separating vascular channels. Large areas of solid proliferations with pronounced atypia and brisk mitotic activity may be completely devoid of vascular architecture. Consistent with their endothelial origin, the cells express a wide range of endothelium specific

P.1324

antigens such as factor VIII, ulex europaeus, CD31, and endothelial growth factor receptor (EGFR-3). CD31 is currently considered to be the most specific endothelial marker.

Figure 35-15 Moderately differentiated angiosarcoma. A,B. Histologic appearance of

moderately differentiated angiosarcoma. Note vascular channels lined by plump endothelial cells. Erythrocytes are seen in the lumen of neoplastic channels. *C,D*. Cytologic features of moderately differentiated angiosarcoma. The spindly tumor cells are arranged in clusters. Note obvious cytologic features of malignancy.

Cytology

Cytologic features of angiosarcomas **depend on the degree of differentiation** (Cho et al, 1997; Boucher et al, 2000). In well-differentiated angiosarcomas, aspirates yield predominantly blood and very scant cellular material. Cytologic preparations of moderately to poorly differentiated tumors are highly cellular and contain **obviously malignant spindle—or epithelioid cells** forming groups and clusters (Fig. 35-15C,D) (Nguyen and Husain, 2000). Aspirates from epithelioid angiosarcomas contain **highly anaplastic epithelioid malignant cells that can be confused with carcinoma** (Ng et al, 1997). In such cases the diagnosis of malignancy is straightforward, but the cellular lineage of differentiation cannot be identified without additional studies.

LESIONS OF PERIPHERAL NERVES

Schwannoma

Pathology and Histology

Schwannomas or **neurilemmomas** are benign peripheral nerve sheath tumors derived from Schwann cells. They involve males and females with equal frequency and are most common between the ages of 20 and 30 years. Schwannomas have unique **predilection for the subcutaneous tissue of the head and neck region** and the extremities. In the trunk they are typically found in the **paraspinal region of the mediastinum and retroperitoneum**. Microscopically, neurilemmoma is composed of Schwann cells forming hyper- and hypocellular areas referred to as Antoni A and Antoni B, respectively. Antoni A areas contain densely arranged spindle cells with twisted nuclei. Antoni B areas consist of sparsely arranged spindle cells within a myxoid stroma. A palisade of tumor cells separated by irregular acellular bands referred to as **Verocay bodies** is a characteristic feature of these tumors (Fig. 35-16A,B). Large, long-lasting tumors may develop degenerative changes such as cysts, calcification, and nuclear atypia. Cellular schwannomas are hypercellular lesions composed predominantly of Antoni A areas, which may be confused with malignant peripheral nerve sheath tumors (Woodruff et al, 1981; Fletcher et al, 1987; Lodding et al, 1990; White et al, 1990). It is important to be aware of the fact that schwannomas practically never undergo malignant transformation.

Cytology

Aspirates from schwannomas contain large clusters of **loosely arranged spindle cells separated by myxoid stroma** (Mooney et al, 1999). Occasionally **palisading arrangement** of tumor nuclei corresponding to **Verocay bodies** can be present (Mentzel et al, 1996; Gupta et al, 2001). Sparse individual spindle cells with elongated nuclei can be also present. Typically such cells show no nuclear atypia or polymorphism (Fig. 35-16C,D) (Henke et al, 1999). Additional examples of schwannomas may be found in Chapters 37 and 40.

Neurofibroma

Pathology and Histology

Neurofibromas are common benign tumors composed of specific **neural fibroblastic cells with elongated wavy nuclei** lying in a loose collagenous stroma (Fig. 35-17A,B). Most neurofibromas are solitary subcutaneous lesions that are not associated with neurofibromatosis. **Plexiform neurofibromas** represent an expansion of nerves by proliferating neurofibroblastic cells grossly mimicking a bag of worms (Iwashita and Enjoji, 1986). Approximately 10% of neurofibromas are associated with **neurofibromatosis (von Recklinghausen's disease)**. The neurofibromas that occur in the settings of neurofibromatosis are multifocal, may involve deep soft tissue and internal organs, and are associated with other stigmata of the disease such as brown (café-au-lait) skin spots. Neurofibromas may become malignant (see below).

Neurofibromatosis is an autosomal-dominant disease that has two distinct clinical forms, each associated with a unique predisposing genetic effect. The peripheral form (type 1) is linked to an alteration leading to functional silencing of the NF1 gene mapping to the pericentromeric region on **chromosome 17**. The central form (type 2) of neurofibromatosis is less frequent and is linked to inactivation of the NF2 gene mapped to **chromosome 22**. The most characteristic features of the two clinical forms of neurofibromatosis are listed in Table 35-3. Microscopically, neurofibromas are characterized by fibrous spindle cells with wavy nuclei separated from each other by loose fibrous or myxoid stroma.

Cytology

Aspirations from neurofibroma yield scanty cellular material and contain sparse, **loosely arranged clusters of wavy spindle cells separated by amorphous myxoid stroma**. The spindle cells of neurofibroma contain elongated **comma-shaped nuclei** with evenly distributed, finely granular chromatin. Muroid material in the background may contain small fragments of collagen bundles (Fig. 35-17C,D) (Hock and Mohamid, 1995).

Malignant Peripheral Nerve Sheath Tumor

Pathology and Histology

Malignant peripheral nerve sheath tumors constitute 5% to 10% of all soft tissue sarcomas and predominantly affect patients between 30 and 50 years of age (Ducatman et al, 1986; Wanebo et al, 1993). More than 30% of the malignant peripheral nerve sheath tumors **develop within preexisting neurofibromas** in the settings of type 1 neurofibromatosis (Herrera and deMoraes, 1984). In most cases, not related to neurofibromatosis, a relationship between the tumor and an adjacent large peripheral nerve could easily be documented. Overall 5-year survival is about 50%, but it decreases to only 15% for tumors involving the trunk. A high rate of local recurrence is caused by the **peculiar ability of the tumor cells to spread along nerve sheaths**. Loss of chromosome 9p followed by CDKN2 gene inactivation is

P.1325

seen in almost 50% of all tumors especially those that represent progression of neurofibroma in type 1 neurofibromatosis. Malignant peripheral nerve sheath tumors typically show the inactivation of both alleles of the NF1 gene, but the exact role of this gene in malignant transformation of neurofibromas is still unclear.

Figure 35-16 Schwannoma. *A,B.* Histologic appearance of schwannoma. Note Verocay bodies created by palisading of the tumor cells. *C,D.* Cytologic details of schwannoma cells. Cells in clusters are separated by abundant stroma. Note degenerative atypia, a distinctive feature for long-lasting tumors (ancient schwannomas). *Inset* shows cells with wavy cytoplasm and coma-shaped nuclei.

Microscopically, the tumor is composed of **spindle cells arranged on long intersecting fascicles reminiscent of fibrosarcoma** (Fig. 35-18A). In some cases these tumors may contain large **areas composed of epithelioid cells** (Fig. 35-18B). Malignant peripheral nerve sheath tumors may contain **heterologous elements**, such as **cartilage** or **osseous**

P.1326

tissue. Composite lesions that contain **neural and rhabdomyoblastic elements** are designated as **Triton tumors**.

Figure 35-17 Neurofibroma. *A,B.* Histologic appearance of neurofibroma. Note wavy cells separated by loose stroma. *C,D.* Cytologic details of neural fibroblastic cells. Note cells with comma-shaped nuclei arranged in loose clusters. Amorphous myxoid stroma separates the cells.

Cytology

Aspirations from malignant peripheral nerve sheath tumors are usually highly cellular and contain tissue fragments and a large number of individual dispersed malignant cells (McGee et al, 1997). The cellular composition depends on degree of tumor differentiation. Thus the **various degree of nuclear atypia and cellular pleomorphism**, ranging from inconspicuous to clearly sarcomatous with pleomorphic and multinucleated malignant giant cells, can be found in these tumors (Fig. 35-18C,D) (Dodd et al, 1997; Jimenez-Heffernan et al, 1999;

P.1327

MD, 1999). **Lesions composed mainly of monomorphic spindle cells may be difficult to distinguish from other spindle cell sarcomas or even benign spindle cell lesions.**

TABLE 35-3 DIAGNOSTIC CRITERIA FOR THE TWO TYPES OF NEUROFIBROMATOSIS

Type 1

Two or more neurofibromas

Six or more café au lait spots ≥ 5 mm in prepubertal patients

Freckles in axillary regions

Optic nerve glioma

Skeletal abnormalities

Parent, sibling, or offspring with type 1 neurofibromatosis

Type 2

Bilateral acoustic nerve schwannomas

First-degree relative with type 2 neurofibromatosis and unilateral vestibular schwannoma or two of the following: neurofibroma, meningioma, glioma, schwannoma, juvenile posterior subcapsular ventricular opacity, and cerebral calcifications

MISCELLANEOUS TUMORS

In this section we describe a series of prototypic soft tissue sarcomas with uncertain histogenesis. These tumors present as unique clinical entities and exhibit distinct microscopic, phenotypic, and molecular features.

Synovial Sarcoma

Pathology and Histology

Synovial sarcoma constitutes 5% to 10% of all soft tissue sarcomas and most frequently affects adolescents and young adults between 15 and 40 years of age (Krall et al, 1981). The vague microscopic resemblance of this tumor and anatomic relation to synovial structures is frequently mentioned in the literature, but whether it originates from synovial lineage or from preformed synovial membrane has never been established. On the **molecular level**, synovial sarcoma is characterized by a reciprocal translocation, t(x:18)(p11: q11), resulting in the formation of a distinct chimeric gene, SSX-SYT (Limon et al, 1991; Dal Cin et al, 1992; Knight et al, 1992). The Xp11 region contains a cluster of closely related SSX1-SSX5 genes, and the Xp11 breakpoint typically involves two of these genes, SSX1 and SSX2 mapping to Xp11.23 and

Xp11.21, respectively (DosSantos et al, 2001). For unknown reasons, SSX1 is involved in the SYT-SSX fusion nearly twice as often as the SSX2. In several cases of synovial sarcoma, a rare SYT-SSX4 fusion has been identified. Several studies have shown that patients with synovial sarcomas with SYT-SSX1 have a longer survival than patients with SYT-SSX2 (Ladanyi et al, 2002) (Fig. 35-19).

Grossly, the tumor is usually sharply circumscribed and multinodular with a tendency for **cysts formation**. The presence of **two morphologically distinct cell populations**, i.e., **epithelial and spindle sarcomatous cells**, contributes to the so-called biphasic appearance of the tumor (Dardick et al, 1991). Depending on the predominance of these elements, synovial sarcoma can be divided into several subtypes: (1) **biphasic**, (2) **monophasic fibrous**, and (3) **monophasic epithelial**. In a typical biphasic synovial sarcoma epithelial cells forming cords, nests, and glandular structures are dispersed in solid compact areas composed of spindle cells (Fig. 35-20A,B). In the monophasic fibrous type, only spindle cells are present with no apparent epithelial component (Fisher, 1986). Additionally, myxoid change, hyalinization in the stroma, hemangiopericytoma-like areas, or calcification may be seen. Poorly differentiated (round cell) type is associated with a more aggressive clinical behavior and in most cases represents a progression of conventional synovial sarcoma. Monophasic epithelioid synovial sarcoma is the rarest subtype and is predominately composed of epithelial elements. Monophasic epithelioid subtypes must be differentiated from true epithelial neoplasms such as adnexal skin tumors or metastatic carcinoma. Most synovial sarcomas are positive for EMA (epithelial membrane antigen) and keratin (Fisher, 1986).

Cytology

Aspirations from synovial sarcoma are highly cellular. In typical biphasic tumors, two populations of cells, i.e., epithelial and spindle cells, can be identified (Kilpatrick et al, 1996b). Fibroblast-like spindle cells contain ovoid nuclei with finely granular, evenly dispersed chromatin and inconspicuous nucleoli (Koss et al, 1992; Viguer et al, 1998). They may form small or large three-dimensional compact clusters with characteristic ragged edges (Ryan et al, 1998). Epithelial cells can be recognized by their polygonal contours and formation of gland-like structures (Fig. 35-20D). Monophasic spindle cell synovial sarcoma contains only spindly sarcomatous cell. In such instances cytologic features overlap with other spindle cells sarcomas (Åkerman, 1996).

Epithelioid Sarcoma

Pathology and Histology

Epithelial sarcoma is a distinctive malignant neoplasm of uncertain histogenesis that is microscopically characterized by a **prominent epithelium-like or epithelioid appearance of tumor cells**. The tumor most frequently affects adolescents and young adults. It has a unique **predilection for subcutaneous and deep soft tissue of hand and forearm and**, less frequently, for the distal portions of the lower extremities (Laskowski, 1961; Dabska and Koszarowski, 1982). In the trunk it is most frequent in the genitourinary region. Clinically it often presents as **multifocal ulcerated cutaneous nodules**. Deep soft tissue lesions are firmly attached to tendons or fascial structures (Chase and Enzinger, 1985). Microscopically the tumor has distinct **nodular architecture with central necrosis and frequently a granuloma-like appearance** (Fig. 35-21A,B). The epithelioid tumor cells with prominent eosinophilic cytoplasm **stain positively for cytokeratins and epithelial membrane antigen (EMA)** (Chase et al,

1984). The clinical course is characterized by multiple recurrences and gradual progression, with eventual metastatic spread to lymph nodes and lungs.

P.1328

Figure 35-18 Malignant peripheral nerve sheath tumor (MPNST). *A*. Histologic appearance of MPNST. Note spindle cells arranged in fascicles. Wavy and comma-shaped nuclei can be seen. Mitotic activity is evident. *B*. Histologic appearance of MPNST with epithelioid features. Clearly malignant polygonal cells possess abundant cytoplasm and rounded nuclei. *C, D*. Cytologic details of MPNST. Note clusters and dispersed cells showing nuclear hyperchromasia and prominent nucleoli. Cells with more abundant cytoplasm may give false impression of epithelial differentiation. *Inset* shows cytologic details of sarcomatous cells with epithelioid features.

P.1329

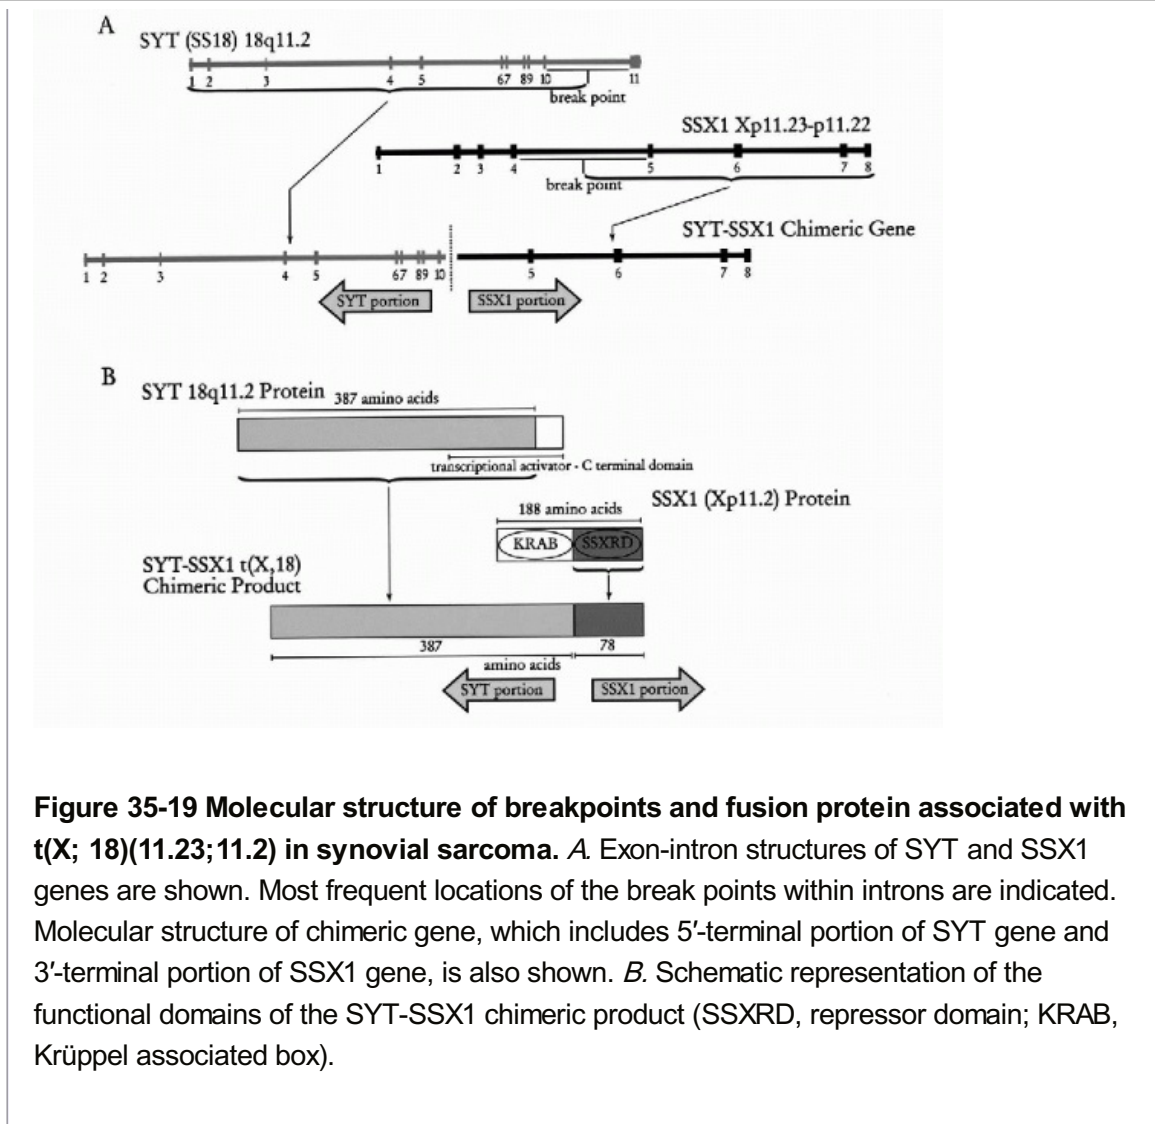

Figure 35-19 Molecular structure of breakpoints and fusion protein associated with t(X; 18)(11.23;11.2) in synovial sarcoma. A. Exon-intron structures of SYT and SSX1 genes are shown. Most frequent locations of the break points within introns are indicated. Molecular structure of chimeric gene, which includes 5'-terminal portion of SYT gene and 3'-terminal portion of SSX1 gene, is also shown. B. Schematic representation of the functional domains of the SYT-SSX1 chimeric product (SSXRD, repressor domain; KRAB, Krüppel associated box).

Cytology

Aspirations from epithelioid sarcoma are highly cellular and contain cells with **abundant eosinophilic cytoplasm** and **large vesicular nuclei** with small but **clearly visible nucleoli** (Hernandez-Ortiz et al, 1995). The epithelioid nature of the cells may not be cytologically obvious and the lesion can be confused with a benign epithelial neoplasm or a reactive histiocytic process (Cardillo et al, 2001; Jogai et al, 2001). The **absence of phagocytic activity and of other inflammatory cells** is a helpful microscopic feature that distinguishes the lesion from a granulation process. Strong positivity for keratins and negative staining for histiocytic markers are the characteristic immunophenotypic features. Overall, the cytologic appearance may be deceptively benign (Fig. 35-21C,D).

Clear Cell Sarcoma

Pathology and Histology

Clear cell sarcoma, also known as **malignant melanoma of the soft parts**, typically involves **tendons and aponeuroses of young adults**. It most frequently presents as a **soft tissue mass of the knee area** (Enzinger, 1968; Chung and Enzinger, 1983). Microscopically the tumor is composed of nests of uniform, rounded to elongated cells with clear cytoplasm and occasional deposits of melanin (Fig. 35-22A,B). Scattered, multinucleated giant cells can be

present (Lucas et al, 1992; Montgomery et al, 1993). Immunohistochemically, the tumor cells are **positive for melanocytic lineage markers** such as S-100 and HMB-45. Prognosis is poor, being characterized by recurrences and eventually distant metastases to the lymph nodes and lungs.

P.1330

Figure 35-20 Biphasic synovial sarcoma. *A,B.* Histologic appearance of biphasic synovial sarcoma. Note well-defined glands composed of epithelial cells. Spindle cell component among glandular structures is seen. *C,D.* Cytologic details of biphasic synovial sarcoma. Spindle cells with obvious atypia (*C*) and epithelial cells creating glands are shown in *D*. *Inset* shows cytologic details of epithelial component.

P.1331

Figure 35-21 Epithelioid sarcoma. *A,B.* Histologic details of epithelioid sarcoma. Note epithelioid appearance and nodular arrangement of sarcomatous cells. *Inset* shows positive immunohistochemical staining for cytokeratin in tumor cells. *C,D.* Cytologic features of epithelioid sarcoma. Note overall bland appearance of sarcomatous cells. Vesicular nuclei containing inconspicuous nucleoli may give false impression of a nonneoplastic condition. *Inset* shows cytologic details of epithelioid sarcomatous cells.

P.1332

Figure 35-22 Clear cell sarcoma (malignant melanoma of the soft parts). *A,B.*

Histologic appearance of clear cell sarcoma. Sarcomatous cells with clear cytoplasm are arranged in nests and fascicles. Note prominent nucleoli. *Inset (upper)* shows multinucleated giant cell. Note similarities between nuclei of clear and giant cells. *Inset (lower)* shows histologic details of nuclear intracytoplasmic inclusion. *C,D.* Cytologic appearance of clear cell sarcoma. Malignant cells show prominent nucleoli. Cytoplasmic melanin pigment is often present. *Inset* shows sarcomatous cells with prominent nucleoli. Note rosette-like arrangements of neoplastic cells.

P.1333

From the molecular point of view the clear cell sarcomas are characterized by (12:22) (q13; q12) translocation resulting in the fusion of the EWS gene to the activating transcription factor 1 (ATF-1) gene. The EWS-ATF-1 chimeric protein consists of the amino-terminal domain of EWS linked to DNA-binding domain of ATF-1 (Panagopoulos et al, 2002). ATF-1 is a member of basic leucine-zipper type transcriptional factor family. It has been recently shown that the chimeric EWS-ATF-1 protein contributes to oncogenesis by suppressing p53-mediated transactivation.

Cytology

Aspirates of clear cell sarcoma contain dispersed oval or spindly tumor cells, containing **large, occasionally eccentric nuclei with prominent nucleoli** (Fig. 35-22C,D). **Large, intranuclear cytoplasmic inclusions** are common (see Fig. 35-22, inset). Scattered multinucleated giant cells may be present in some cases (Creager et al, 2002; Tong et al, 2002). Rarely the tumor cells may form small, rosette-like groups (Fig. 35-22, bottom inset).

Alveolar Soft Part Sarcoma

Pathology and Histology

Alveolar soft part sarcoma is a rare neoplasm typically arising in the deep soft tissue of lower extremities or in the head and neck area but sometimes in other organs as well. It primarily affects adolescents and young adults. Microscopically, it is characterized by the presence of nest or gland-forming **tumor cells with abundant granular cytoplasm** resulting in a pseudoalveolar pattern (Fig. 35-23A,B). Vascular channels lined by a single layer of endothelial cells separate these cellular aggregates. Neoplastic cells are large, polygonal or round with a centrally located nucleus and a predominant nucleolus. Periodic acid-schiff (PAS)-staining shows intracellular glycogen and **rhomboid crystals** (Evans, 1985; Auerbach and Brooks, 1987). The PAS-positive protein crystals of unknown origin, best visualized by electron microscopy are characteristics of this tumor. Clinically, these tumors are highly aggressive, with early onset of local recurrence and distant metastases, primarily to the lungs.

Immunohistochemically alveolar soft part sarcoma co-expresses vimentin, muscle-specific actin, and desmin and are negative for cytokeratins and EMA (Mukai et al, 1986; Rosai et al, 1991).

Alveolar soft part sarcoma carries a distinct chromosomal translocation involving (X;17) (p11;q25), resulting in formation of a TFE3-ASPL chimeric gene (Ladanyi et al, 2001). The significance of this observation is still unknown.

Cytology

The information on cytology of this rare tumor is limited to a few case reports. In our experience the alveolar soft part sarcoma yields highly cellular smears, containing **large oval cells with dense eosinophilic granular cytoplasm and vesicular nuclei with prominent nucleoli**. **Binucleated and multinucleated cells** can also be present (Logrono et al, 1999b). The abundant granular cytoplasm of the tumor cells is frequently disrupted during aspiration and smearing, creating the fine "dirty" background (Husain and Nguyen, 1995). Overall cytologic features may overlap with those of **epithelioid or clear cell sarcomas, melanoma**, and even metastatic carcinoma (Fig. 35-23C,D).

Desmoplastic Small Cell Tumor

Pathology and Histology

Desmoplastic small cell tumor is a recently recognized **distinct malignant neoplasm** composed of small cells. The tumor usually occurs in young adults and most frequently involves the abdominal cavity (Gerald et al, 1991). A distinctive microscopic feature is the presence of **well-demarcated nests of small tumor** cells surrounded by a prominent band of connective tissue stroma. Immunohistochemically, the tumor exhibits unique coexpression of cytokeratins and desmin (Palmer et al, 2001; Panagopoulos et al, 2002). The tumor is frequently

unresectable at presentation, and the majority of patients die within 24 months of the diagnosis (Layfield and Lenarsky, 1991; Ordoñez et al, 1993).

Desmoplastic small cell tumor is pathogenetically related to Ewing's sarcoma/PNET in that it often exhibits translocation of chromosomes 11 and 22, and EWS is one of the partner genes involved in the breakpoint. However, the second partner of the fusion involves the WT-1 gene mapped to 11p13 (Sawyer et al, 1992; Biegel et al, 1993; Rodriguez et al, 1993; Ladanyi and Gerals, 1994). The tumor and its cytologic presentation are discussed in Chapter 26 as a primary tumor of serous membranes.

The differential diagnosis includes other small blue round cell tumors such as Ewing sarcoma/PNET, neuroblastoma, Wilms' tumor, rhabdomyosarcoma, lymphoma, and small cell carcinoma.

Benign Lesions Mimicking Soft Tissue Sarcomas

In this section we describe the two benign reactive conditions of soft part that may be confused with sarcoma. The unifying theme of these lesions is a **proliferation of fibroblastic and/or osteoblastic cells**, which may show significant cytologic and architectural atypia leading to incorrect diagnosis of malignancy.

Nodular (Pseudosarcomatous) Fascitis

Pathology and Histology

Nodular fascitis is a common reactive proliferation of fibroblasts, **often confused with spindle cell sarcoma**. Usually, it affects adults between 20 and 40 years of age and presents as a **rapidly growing subcutaneous mass** (Iwasaki and Enjoji, 1975). Although it can affect any anatomic site, nearly half of the cases presents as a soft tissue mass of the **volar aspect of the forearm** (Bernstein and Lattes, 1982). Nodular fascitis involving the **head and neck** with frequent secondary involvement of the underlying bone (cranial fascitis)

P.1334

is common in infants and children. On the basis of location, nodular fascitis can be divided into three types: **subcutaneous**, **intramuscular**, and **fascial** (Meister et al, 1978a). Regardless of type, it consists of young growing fibroblasts arranged in short bundles with a myxoid or hyaline matrix. The fibroblasts show rapid growth features with spindly or trapezoid cytoplasm, large nuclei and nucleoli and high mitotic activity (Fig. 35-24A,B) (Montgomery and Meis, 1991). Some of the mitoses may be atypical (see Chap. 6). Occasionally, foamy histiocytes and lymphocytes are present. The lesion is ill defined and has overall star-like architecture, with radiating prominent capillary vessels. This benign reactive condition is typically cured by local excision, and sometimes regresses spontaneously.

Figure 35-23 Alveolar soft part sarcoma. *A,B.* Histologic details of alveolar soft part sarcoma. Note alveolar structures of neoplastic cells surrounded by rich vascular network. *C,D.* Cytologic details of alveolar soft part sarcoma. Monotonous population of malignant cells with abundant cytoplasm. Note vesicular nuclei with prominent nucleoli. Binucleated cells are evident.

P.1335

Figure 35-24 A,B. Histologic details of nodular fascitis. Note proliferating fibroblasts arranged in short bundles. **C,D. Cytologic features of nodular fascitis.** Note large clusters of spindle cells and some mucoid material in the background. Spindle cells look similar to fibroblasts in granulation tissue. *Inset* shows cytologic details of spindle cells. Note the absence of nuclear atypia and admixture of inflammatory cells.

Cytology

Aspirates from nodular fascitis are highly cellular and contain a mixture of elongated spindly cells occurring singly or forming large clusters. The elongated, sometimes **almost cuboidal** cells with trapezoid cytoplasm, **plump nuclei**, and **prominent nucleoli** resembling tissue culture fibroblasts are characteristic of this condition (Maly and Maly, 2001). It is of note that the configuration of tumor cells is fairly constant (Fig. 35-24D and inset). This feature may prevent the common error of mistaking this benign lesion for a sarcoma where a greater diversity of cells occurs. An admixture of inflammatory cells is usually present. Some myxoid substance in the background is usually found (Fig. 35-24C,D) (Aydin et al, 2001).

Myositis Ossificans

Pathology and Histology

Myositis ossificans represents a **benign ossifying process of musculature**, usually occurring after injury in young adults. Depending on the phase of the disease, the clinical, radiographic, and microscopic pictures can differ. Morphologically, the **early phases** show immature vascular fibroblastic granulation-like tissue, with a mild to moderate degree of polymorphism, high mitotic activity, and scattered multinucleated giant cells. The **intermediate phase** shows a mixture of fibroblasts, osteoblasts, and osteoid, with some predilection for the periphery of the lesion. **Mature lesions** are composed of lamellar bone, with at least focal osteoblastic rimming and dense fibroblastic tissue (Acherman, 1958). The microscopic hallmark of myositis ossificans is its zonal architecture with mature bone present more likely to be located at the periphery of the lesion than in the center. The bone produced in myositis ossificans eventually forms a shell-like structure best seen on specimen radiographs (Nuovo, 1992). Conservative excision is usually curative, but incompletely excised lesions may recur.

Cytology

Again the experience with aspiration cytology of these rare lesions is very limited (Dodd and Martinez, 2001). Upon entering the lesion with the needle, the presence of bony spicules and calcium may give a “gritty” sensation that in itself may suggest this lesion. The smears may contain fibroblasts, multinucleated giant cells and fragments of osteoid that should not be mistaken for hyaline tissue or amyloid. The giant cells may mimic those seen in giant cell tumors of bone (see Chap. 36). Roentgenologic and clinical findings are essential in the recognition of this lesion.

Bone Tumors

Bogdan Czerniak

Tomasz Tuziak

Andrzej Kram

Alberto Ayala

Primary bone tumors, excluding lymphohematopoietic malignancies, constitute only 0.2% of all tumors and occur at a rate of approximately one tenth that of the closely related soft-tissue sarcomas. The overall incidence rate is approximately 0.8/100,000 (Dorfman and Czerniak, 1995). The first well-defined peak occurs during the second decade of life, and the second peak occurs in patients older than 60 years (Fig. 36-1). This bimodal age-specific incidence rate pattern of bone sarcomas is clearly different from that of soft-tissue sarcomas, which gradually increases with age.

Because bone tumors of different types often have overlapping microscopic features, evaluating them without clinical and radiographic context may result in an incorrect diagnosis. Therefore, they should be approached as clinicopathological entities whose behavior and biological potential must be assessed by both microscopic details and clinical factors such as patient age, location in a particular skeletal site, specific radiographic presentation, and association with underlying conditions (Sanerkin and Gallagher, 1979). As is the case with soft-tissue sarcomas, **we advocate a multimodal approach to establish the diagnosis with a stepwise analysis of clinical, radiographic, microscopic, and, in selected cases, molecular data.** Such a multidimensional analysis is more likely to result in a clinically valid assessment of the lesion (Saeter, 2003).

A diagnostic specimen can be obtained by open biopsy or various transcutaneous (closed) biopsy techniques (de Santos et al, 1978). The use of the latter techniques, which are often assisted by radiographic imaging techniques, has dramatically increased in many institutions. Aspiration cytology, combined with core-needle biopsy, is often used as a preliminary diagnostic approach to bone lesions, and in many cases it yields adequate material to establish the final diagnosis (deSantos et al, 1979b; Ayala et al, 1995; Collins et al, 1998a; Agarwal et al, 2000). However, some bone lesions are extremely difficult or even impossible to diagnose on the basis of the small amount of material obtained by core-needle biopsies or fine-needle aspirates. In such instances, an open biopsy must be performed.

Aspiration biopsy of bone lesions is one of the oldest diagnostic applications of this technique. Coley et al (1931) described their findings in 35 patients, with remarkably accurate results. In Argentina, Schajowicz and Lemos (1970) collected several thousand patients for whom the primary diagnosis was established by aspiration rather than by open biopsy. Because the cytologic sampling may be tedious, the

contemporary trend is to perform core-needle biopsies under radiologic guidance and examine the residual material in the form of smears.

Except for bone lesions in **multiple myeloma**, which are routinely aspirated for diagnosis, the aspiration biopsy is principally used to confirm the nature of suspected, relatively uncommon, primary, or (more commonly) metastatic bone tumors. In metastatic cancer, the site of origin may be sometimes determined in smears. Aspirations are rarely used to diagnose inflammatory or reactive conditions of the skeleton, which include **osteomyelitis** (caused by *Staphylococcus* or *Mycobacterium tuberculosis*), **exuberant fracture callus**, and other trauma-related lesions.

Planning the biopsy approach (open or closed) is a complex process that must take into account the technical aspects of subsequent definitive surgery. An inappropriately selected biopsy site may preclude limb-sparing definitive surgery. In general, the location of the biopsy track should be such that if the lesion proves to be malignant, it can be excised en bloc with the segment of affected bone. This is particularly important if limb-salvaging procedures are to be successful. It is generally recommended that preoperative diagnostic procedures should be performed at medical institutions that can provide definitive treatment (Simon et al, 1986; Raymond et al, 1995).

In this chapter, we provide an overview of bone lesions, focusing on those conditions that are primary targets for aspiration cytology. Benign lesions will be discussed only as points of differential diagnosis.

TECHNIQUES OF ASPIRATION BIOPSY

Aspiration biopsy of bone lesions has special requirements. To perforate the cortical bone, a thick needle (external diameter = 1.2 to 1.5 mm) with a stylet is used as a guide for the thin needle. The skin and the subcutaneous tissue are locally anesthetized to the level of the

periosteum. Subsequently, the thick needle is inserted through the bone to the periphery of the lesion. The stylet is withdrawn and a thin needle is introduced into the target through the guide. The aspiration then proceeds as in any other organ (see Chap. 28).

A brief period of general anesthesia is required under the following circumstances:

- The tumor causes a great deal of pain or is painful on palpation.
- A vertebral body is the target of aspiration.
- The aspiration is performed on a child.

Smaller lesions are often aspirated under the guidance of fluoroscopy or computed tomography (CT), which requires close cooperation with the radiologist. Large, palpable lesions of the long bones or the sternum can be aspirated without x-ray monitoring.

Thin-needle aspirates of bone lesions often yield a large amount of blood that may enter the lumen of the syringe. Smears prepared from such material are commonly of scant cellularity. The methods used to secure diagnostic cells from bloody specimens are described in Chapter 28.

OSTEOBLASTIC LESIONS

Osteoblastic or bone-forming lesions can be divided into three major categories. The first category includes lesions that are clinically benign and practically never recur after simple excision. The intermediate group consists of lesions with locally destructive growth and a high recurrence rate,

P.1342

but virtually no metastatic potential. The third category comprises frankly malignant tumors with a high propensity for distant metastasis. Some locally aggressive bone-forming tumors may progress, typically after many recurrences, to highly aggressive sarcomas. The phenomenon is similar to the progression of low-grade chondrosarcoma to dedifferentiated chondrosarcoma (Abdelwahab et al, 1997; Reith et al, 1999). Among bone-forming lesions, areas of anaplasia are frequently seen in low-grade intramedullary osteosarcoma and low-grade bone surface (parosteal) osteosarcoma (Wold et al, 1984; van Oven et al, 1989; Abdelwahab et al, 1997; Shuhaibar and Friedman, 1998; Reith et al, 1999).

Benign osteoblastic lesions were first recognized as a distinct group by Jaffe and Mayer (1932). The identification of **osteoid osteoma** as a distinct entity came later, in a report by Jaffe (1935). Jaffe (1956) and Lichtenstein (1956) independently described **osteoblastoma** to delineate osteoblastic tumors with greater growth potential than osteoid osteoma. More recent experience with benign osteoblastic tumors has indicated that some lesions may reach a considerable size, exceeding 4 cm in diameter. These lesions have a locally destructive growth pattern with a high recurrence rate after curettage, and are referred to as **aggressive osteoblastomas** (Miyayama et al, 1993).

The three main categories of benign osteoblastic tumors—osteoid osteoma, osteoblastoma, and aggressive osteoblastoma—represent a continuum of lesions with different growth potentials, levels of extrinsic humoral activity, and recurrence rates (Fig. 36-2). Osteoid osteomas and osteoblastomas have nearly identical microscopic features and thus cannot be distinguished from one another by microscopy alone. Some authors have proposed that lesions larger than 1.5 cm in diameter should be classified as osteoblastomas. In contrast, aggressive osteoblastoma, in addition to its larger size (>4 cm), is characterized by the presence of so-

called epithelioid osteoblasts (Schajowicz and Lemos, 1970; Lucas et al, 1994).

Osteosarcoma is a prototypic malignant bone-forming tumor, and the most common primary sarcoma of bone. This term is used to describe a heterogeneous group of lesions with diverse morphologies and clinical behaviors. Designations such as osteoblastic, chondroblastic, and fibroblastic osteosarcoma reflect the microscopic variability of the tumors and the presence of histologically different components within one lesion (Inwards and Unni, 1995). Osteosarcoma may originate and grow primarily inside the bone (**intramedullary osteosarcoma**) or it may grow on the surface on bone (**surface osteosarcoma**) within periosteal or paraosteal tissue (Ahuja et al, 1977; Bertoni et al, 1982; Okada et al, 1994). The currently recognized types of osteosarcoma and the descriptive terms used in their diagnosis are listed in Table 36-1.

Figure 36-2 Benign osteoblastic tumors. Comparative features of biologic behavior and growth. (From H. Dorfman and B. Czerniak, *Bone Tumors*, Mosby, Inc., St. Louis, 1998).

Osteoid Osteoma

Osteoid osteoma is a benign tumor that consists of a well differentiated bone-forming nidus surrounded by a distinct zone of reactive bone sclerosis. The nidus has limited growth potential and usually is less than 1 cm in diameter (Jaffe, 1935; Gitelis and Schajowicz, 1989). Osteoid osteomas are relatively common lesions that account for approximately 10% of all primary bone tumors. They usually affect teenagers and young adults at a male-to-female ratio of 3:1.

Osteoid osteoma has characteristic, often diagnostic, clinical symptoms. In the vast majority of cases, patients present with **pain of increasing severity** that is relieved by aspirin or other nonsteroidal antiinflammatory agents. Approximately 50% of osteoid osteomas involve the long bones of the lower extremity, with the femoral neck being the most frequent site (Gitelis and Schajowicz, 1989.) They also frequently affect the small bones of the hands and feet. In contrast to osteoblastomas, they occur infrequently in the spine. Microscopically, the nidus consists of an interlacing network of bone trabeculae with different levels of mineralization rimmed by prominent osteoblasts with occasional multinucleated giant cells (Schajowicz and Lemos, 1970).

Osteoblastoma

Osteoblastomas occur approximately one third less frequently than osteoid osteomas. They affect individuals with an age peak incidence in the second decade of life, and the male-to-female ratio is approximately 3:1. These tumors have a predilection for the axial skeleton and

frequently involve the vertebral column, sacrum, and craniofacial bones (Schajowicz and Lemos, 1970).

Radiographically, osteblastomas are similar to osteoid

P.1343

osteomas. They present as a lytic, well demarcated lesion surrounded by a zone of reactive sclerosis with a nidus exceeding 1.5 cm in diameter (Jaffe, 1956; Lichtenstein, 1956) (Fig. 36-3A).

TABLE 36-1 TYPES OF OSTEOSARCOMA AND DESCRIPTIVE TERMS USED IN THEIR DIAGNOSIS

Intramedullary osteosarcoma
Conventional
Osteoblastic
Chondroblastic
Fibroblastic
Malignant fibrous histiocytoma-like
Osteoblastoma-like
Giant-cell-rich
Small-cell
Epithelioid
Telangiectatic
Well-differentiated (low-grade intraosseous)
Secondary osteosarcoma
Paget's disease
Postradiation
Bone infarct

Fibrous dysplasia

Metallic implant

Chronic osteomyelitis

Osteosarcoma associated with specific clinical syndromes

Familial

Rothmund-Thomson syndrome

Retinoblastoma

Multifocal

Surface osteosarcoma

Paraosteal (juxtacortical)

Periosteal

High-grade surface (de novo and dedifferentiated)

Intracortical osteosarcoma

Grossly, the nidus appears as a granular, friable, reddish tissue with secondary changes due to hemorrhage and cystic degeneration.

Microscopically, the nidus is similar to an osteoid osteoma nidus, consisting of a network of bone trabeculae distributed in loose fibroblastic stroma with prominent vasculature (Lucas et al, 1994) (Fig. 36-3B). Multinucleated giant cells and rimming osteoblasts are present (Schajowicz and Lemos, 1970; Ruggieri et al, 1996).

Aggressive Osteoblastoma

Pathology and Histology

Aggressive osteoblastomas are extremely rare tumors that are considered as borderline lesions between benign osteoblastomas and osteosarcomas (Dorfman and Weiss, 1984). They have a higher growth potential than conventional osteoblastomas, and typically exceed 4 cm in diameter. Clinically, aggressive osteoblastomas are characterized by destructive growth and high risk for recurrence, but they have virtually no metastatic potential.

Microscopically, the presence of so-called epithelioid osteoblasts is the main histological difference between conventional and aggressive osteoblastomas (Miyayama et al, 1993).

Epithelioid osteoblasts are round cells with abundant eosinophilic cytoplasm and an

eccentrically located, large, oval nucleus with a prominent nucleolus. The nucleus is often displaced by a clear cytoplasmic area, which ultrastructurally represents an enlarged Golgi apparatus.

Cytology

Osteoid osteomas are practically never diagnosed by cytology. Aspirations of benign osteoblastic lesions are typically performed on larger lesions involving deep anatomic sites that require major surgery for an open biopsy (Fig. 36-3A). Aspirations from osteoblastoma are highly cellular and contain **oval osteoblastic cells with eccentric nuclei and dense eosinophilic cytoplasm (epithelioid osteoblasts)** (Fig. 36-3D). Some of these cells contain a well demarcated **cytoplasmic halo** representing a prominent Golgi center, a feature frequently seen in activated osteoblastic cells (Fig. 36-3, upper inset). Scattered multinucleated giant cells are usually present. Mitotic figures are rare. No atypical mitoses or nuclear pleomorphism can be seen. Aggressive osteoblastoma should be considered if an aspirate from an osteoblastic lesion, exceeding 4 cm in diameter, contains a large population of enlarged epithelioid osteoblasts with some nuclear pleomorphism and more than occasional mitotic figures.

Osteosarcoma

Pathology and Histology

Osteosarcoma is a malignant tumor of bone in which malignant mesenchymal cells have **the ability to produce osteoid matrix or immature bone** (Unni, 1998).

It accounts for approximately 20% of all primary sarcomas of bone, excluding multiple myeloma and hematopoietic neoplasms. The most frequent sites of skeletal involvement and the peak age incidences are shown in Figure 36-4. The age distribution is bimodal, with the first peak occurring during the second decade of life, and the second, smaller peak occurring in patients older than 50 years. The incidence within the specific bone corresponds to the site of greatest growth rate. Accordingly, the **distal femoral and proximal tibial metaphyses are the most common sites for osteosarcoma**. The humerus is the third most frequently involved bone, with the majority of cases involving the proximal humeral metaphyses. Other, less frequent locations include the axial skeleton, craniofacial bones, and pelvis (Clark et al, 1983). This description is limited to the most frequent conventional high-grade intramedullary form of osteosarcoma frequently diagnosed by aspiration cytology.

P.1344

A more comprehensive description of all variants of osteosarcoma is beyond the scope of this review.

Figure 36-3 Osteoblastoma of the vertebral column. *A.* Computer tomogram shows a lytic destructive tumor containing foci of mineralized bone matrix that involve the pedicle and lamina of the thoracic vertebra. It expands into the spinal canal, displacing a dural sac and compressing the spinal cord. *B.* Microscopic features of osteoblastoma composed of irregular bony trabeculae rimmed by prominent osteoblastic cells. Note the stroma with prominent dilated vascular channels and scattered multinucleated osteoclastic giant cells. *C.* Fine-needle aspirate showing scattered multinucleated giant cells and multiple mononuclear epithelioid osteoblastic cells with a prominent eosinophilic cytoplasm. *Inset.* Higher magnification of a multinucleated giant cell with centrally clustered oval nuclei containing prominent nucleoli. *D.* High magnification of epithelioid osteoblastic cells with prominent oval densely eosinophilic cytoplasm and peripherally located nuclei containing discrete nucleoli. Note that some of the cells contain double nucleoli. *Inset.* Higher magnification of osteoblasts. Some of them show ill-defined cytoplasmic lucency (arrow) corresponding to a prominent Golgi center. (*B-D*: H&E.)

Although the vast majority of osteosarcomas are de novo lesions, approximately 10% to 15% of them arise in patients with rare **clinical syndromes**, such as **familial osteosarcoma**, **retinoblastoma-associated osteosarcoma**, **Rothmund-Thomson syndrome**, and **multifocal osteosarcoma**. Some tumors may develop in association with several neoplastic and nonneoplastic precursor lesions (Dick et al, 1982; Haibach et al, 1985; Hansen et al, 1985). Familial osteosarcoma occurs in several generations of families that are most frequently affected by retinoblastoma (Draper et al, 1986). Li-Fraumeni syndrome is another familial

cancerpredisposing syndrome in which a germ line mutation of

P.1345

the tumor-suppressor gene p53 is associated with a high incidence of osteosarcoma (Garber et al, 1991). Rothmund-Thomson syndrome is a very rare condition characterized by lesions of the skin, eye, genitals, central nervous system, and bone. This disorder predisposes an individual to squamous cell carcinoma of the skin and osteosarcoma, which may be multicentric.

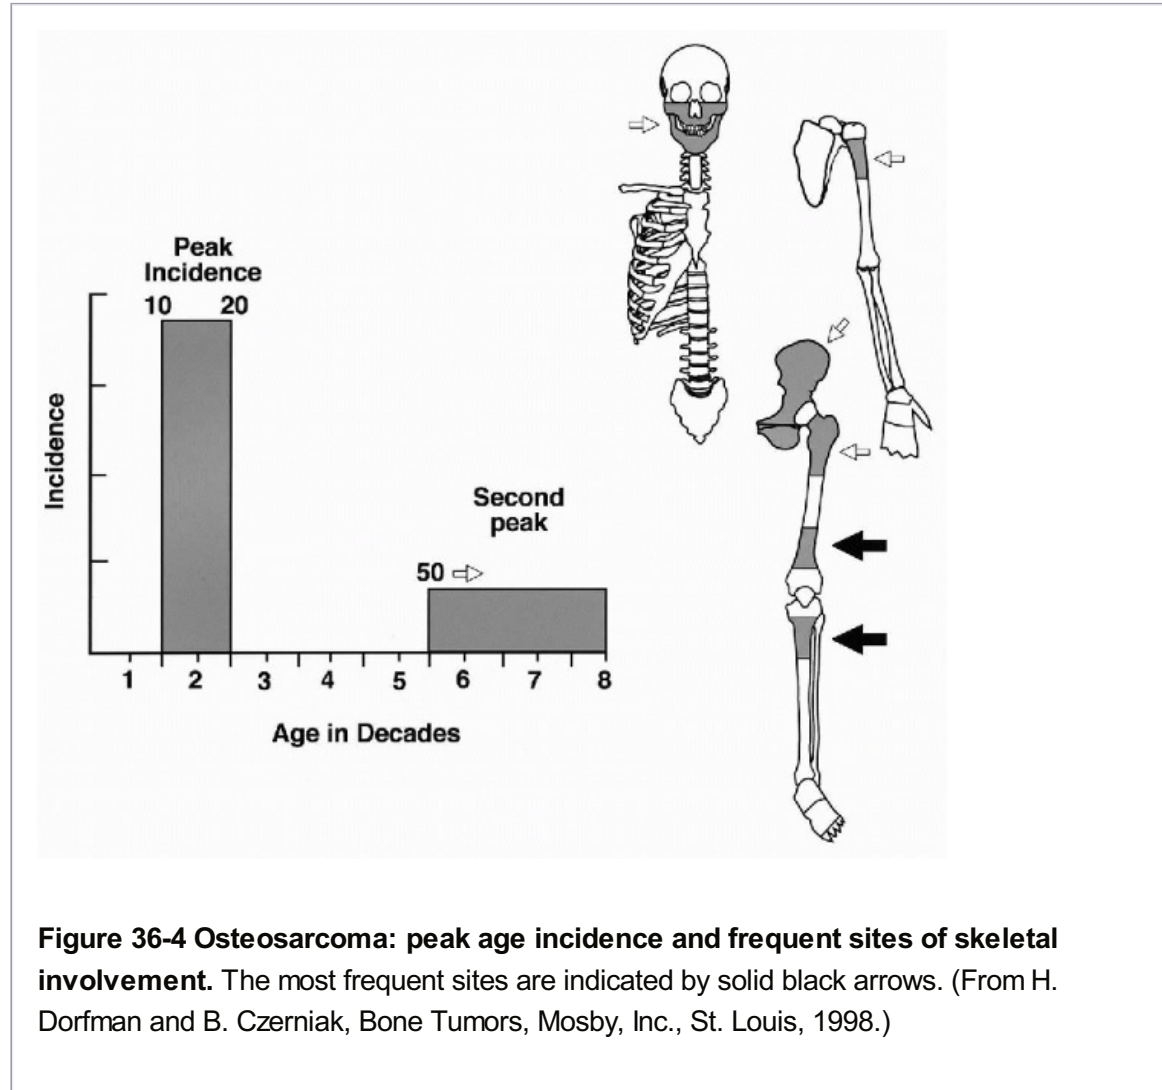

Figure 36-4 Osteosarcoma: peak age incidence and frequent sites of skeletal involvement. The most frequent sites are indicated by solid black arrows. (From H. Dorfman and B. Czerniak, *Bone Tumors*, Mosby, Inc., St. Louis, 1998.)

Paget's disease is the most frequent nonneoplastic precursor lesion of osteosarcoma in older patients (Haibach et al, 1985). Osteosarcomas complicating Paget's disease are usually of high grade and most frequently involve the pelvis, humerus, and femur. In general, secondary osteosarcomas that complicate predisposing conditions are associated with a significantly worse prognosis than conventional de novo high-grade osteosarcomas. **Radiation-induced osteosarcomas** develop with a latency period of 3 years or more after radiation treatment; most such tumors are of high grade and follow an aggressive course with short survival (Sim et al, 1972). Bone infarcts rarely give rise to osteosarcomas. A small number of high-grade osteosarcomas have been reported in patients who have received **metallic prosthetic implants** (Martin et al, 1988). Other nonneoplastic conditions, such as fibrous dysplasia and chronic osteomyelitis, are associated with a very low incidence of secondary malignancy (Johnston and Miles, 1973).

Current multidrug chemotherapeutic regimens substantially reduce tumor mass in at least 50%

of patients; in some of these patients, complete or near complete necrosis can be accomplished. The latter is associated with a substantially better prognosis compared to a tumor that responds less favorably to chemotherapy (Raymond et al, 1987). Thus, **pathologic assessment of chemotherapy effect** is now universally accepted as an integral element of the multimodal approach (Ayala et al, 1984). Moreover, the degree of necrosis in the postchemotherapy specimen is used as a factor in modifying the postoperative treatment protocol (Raymond et al, 1995).

The **radiographic presentation** of osteosarcoma varies greatly, from completely lytic to sclerotic lesions, but typically the combination of these features enables a radiographic diagnosis to be established (Sweet et al, 1981; deSantos and Edeiken, 1982; Sundaram et al, 1987). The production and mineralization of the bone matrix by the tumor results in cloudy opacities that vary in size, shape, and density (Fig. 36-5A). These opacities may be uniformly distributed throughout the lesion or they may cluster in one or several areas of the tumor. Occasionally, osteosarcoma can present as a large, solid, ivory-like sclerotic mass with heavy mineralization. The growth pattern is destructive, with ill-defined boundaries between the tumor and normal bone (Madewell et al, 1981). Usually the cortex is at least partially, or more often completely, disrupted. In such instances, the tumor extends to subperiosteal tissue and elevates the periosteum, forming the so-called **Codman's triangle**. An obvious extension of tumor into the periosteal soft tissue is seen in the majority of such cases (deSantos et al, 1979a; Ragsdale et al, 1981).

The **gross appearance** of osteosarcoma is best described in its typical location, i.e., in the metaphyseal portion of a long bone. A combination of bony and soft-tissue areas is responsible for the heterogeneous appearance of the tumor, which has areas that vary in color, consistency, and degree of ossification (Fig. 36-5B). Heavily ossified areas are ivorycolored and can be as hard as normal cortical bone. Less ossified lesions are soft, fleshy, and lighter yellow (deSantos and Edeiken, 1982). The tumor exhibits an invasive, bone-destructive growth pattern. Small lesions are usually eccentrically located and attached to the inner surface of the cortex. More advanced lesions fill the medullary cavity and show evidence of cortical destruction with elevation of periosteum and extension into the soft tissue.

P.1346

Figure 36-5 Osteosarcoma of the proximal tibial metaphysis. *A.* T₁-weighted magnetic resonance (MR) image shows extensive cortical destruction and extension of the tumor into soft tissue and the epiphysis, with inhomogeneous signal. *Inset.* Coronal T₁-weighted MR image shows an inhomogeneous medullary tumor with circumferential extension to the periosteal soft tissue. *B.* Gross photograph of frontal section of same tibial resection specimen after limb salvage procedure shows heavily ossified tumor with circumferential extension into the periosteal soft tissue. The tumor is heterogeneous with heavily ossified ivory-like areas centrally and less ossified soft-fleshy and gritty appearance peripherally. *C.* Histologic features of high-grade osteosarcoma showing spindle malignant cells producing immature osteoid. *D.* Histologic features of a high-grade osteosarcoma with abundance of immature tumor bone deposited by osteoblastic tumor cells. *E.* Fine-needle aspirate containing large irregular clusters of highly pleomorphic sarcomatous cells. *Inset.* Abnormal mitotic figure. *F.* High magnification of anaplastic sarcomatous cells forming loosely arranged clusters with brisk mitotic activity. Inset shows a multinucleated giant tumor cell. *G.* Higher magnification of anaplastic, somewhat epithelioid sarcomatous cells with pronounced atypia and mitotic activity. (*C-G:* H&E.)

The microscopic findings may vary considerably from lesion to lesion and from area to area.

Evidence of direct production of an osteoid matrix by sarcomatous cells is required before a lesion can be classified as an osteosarcoma. The relations between two tumor

components—the tumor cells and an extracellular matrix—are very important for diagnosis.

According to the predominant type of matrix involved, the osteosarcoma is subdivided into three main categories: **osteoblastic**, **chondroblastic**, and **fibroblastic** (Dahlin and Unni, 1977; Unni and Dahlin, 1989). Osteosarcoma frequently presents as an undifferentiated sarcoma with predominant pleomorphic, round, or spindle cells showing only scattered foci of osteoid production. The tumor cells may have densely eosinophilic cytoplasm with eccentrically placed nuclei, and resemble osteoblasts, but are usually larger than normal or even activated osteoblasts. These cells may infiltrate the medullary cavity or extraosseous tissue in a dispersed manner or they may grow in large cohesive sheets with epithelioid features (Yoshida et al, 1989).

Figure 36-6 Patterns of osteoid depositions in osteosarcoma. A. Thick trabecula of osteoid between sarcomatoid tumor cells. B. Higher magnification of A showing coarse,

well developed trabeculae of immature osteoid within sarcomatoid tumor cells. *C.* Early lace-like osteoid bands between sarcomatoid tumor cells. *D.* Higher magnification showing a border between anaplastic tumor cells and a solid area of osteoid.

The osteoblastic nature of the tumor cells is best recognized by close appositions of sarcomatous cells to tumor bone trabeculae, or by their entrapment in lace-like osteoid depositions (Fig. 36-6A-D). It is important to remember that osteosarcoma can show the whole spectrum of sarcomatous

P.1348

features, from small and undifferentiated, to oval and spindle-shaped, to highly pleomorphic neoplasms (Edeiken et al, 1987; Ayala et al, 1989; Nakajima et al, 1997). As in other high-grade sarcomas, a prominent **vascular hemangiopericytoma-like pattern** can be found. Numerous atypical mitoses are usually present. At the opposite end of the spectrum are highly ossified sclerosing lesions in which a full range of tumor bone production can be observed.

Osteosarcoma can also exhibit **cartilaginous differentiation**. In some instances, the cartilaginous component may be extensive and dominant throughout the lesion, but even in predominantly chondroid tumors, at least focal direct osteoid production by sarcomatous tumor cells can be found. Tumors with predominantly chondroblastic features are frequently found in the craniofacial bones. The fibroblastic type of osteosarcoma is characterized by the presence of a predominant spindle-cell component similar to that seen in fibrosarcoma. The production of osteoid by fibroblast-like cells discloses the bone-forming nature of these lesions and helps to differentiate them from other spindle-cell neoplasms of the bone (see Table 36-1).

Cytology

Aspirates from osteosarcomas are usually, but not always, highly cellular and contain frankly malignant mesenchymal cells arranged in large clusters and smaller groups, or individually dispersed (see Fig. 36-5E-G). Osteosarcoma cells are spindled, oval, rounded, epithelioid, or pleomorphic, and show a high degree of cellular atypia. The malignant cells often have abundant dense cytoplasm and large nuclei containing prominent nucleoli that do not show any specific feature of osseous differentiation. The overall cytologic picture, in most instances, is **indistinguishable from that of a pleomorphic malignant tumor**, such as a malignant fibrous histiocytoma (Hakky et al, 1990). Cytologic preparations from osteosarcoma may contain variable amounts of collagen that mimics an osteoid. Fragments of cartilage matrix, as well as multinucleated giant cells, may also be present (Ellison et al, 1996). In general, a correlation of cytologic findings with clinical and radiographic presentations permits a preoperative cytologic diagnosis of osteosarcoma to be established in most cases (White et al, 1988).

TUMORS OF CARTILAGE

Tumors of cartilage can be benign or malignant. Benign cartilaginous lesions can be **reactive, neoplastic, hamartomatous, or dysplastic** in nature. In all of these conditions, proliferating cartilage cells may show cytologic atypia, and thus evaluations of these lesions that disregard the clinical and radiological contexts may lead to serious diagnostic errors (Bonnevialle et al, 1988). The rare cartilage-containing reactive lesions, such as **synovial chondromatosis, florid reactive periosteitis, bizarre parosteal osteochondromatous proliferations, acquired osteochondroma, subungual exostosis, and pubic osteolysis**, are all characterized by proliferation of cartilage, which may show pronounced atypia (Bendl, 1980;

Spjut and Dorfman, 1981; Nora et al, 1983; Lindeque et al, 1990; Meneses et al, 1993; Edeiken et al, 1994). **Chondroma** is a prototypic, benign cartilage neoplasm that most frequently involves the medullary cavity and rarely presents as a subperiosteal (juxtacortical) lesion (Bauer et al, 1982). **Enchondromatosis** represents a dysplastic cartilage condition and occurs in two clinical settings: **Ollier's disease** and **Maffucci syndrome**. The lesions of cartilage in these conditions may show pronounced atypia (Lewis and Ketcham, 1973; Cannon and Sweetnam, 1985). **Chondroblastoma** and **chondromyxoid fibroma** are two examples of benign neoplasms. They are characterized by the **presence of immature cartilage cells**, which may focally produce extracellular cartilaginous matrix. Developmental cartilage anomaly of the hamartomatous type is represented by **osteochondroma**, which may be solitary or multiple.

Chondrosarcoma is the term given to a heterogeneous group of cartilage tumors that are characterized by diverse morphologic features and clinical behaviors, which range from **locally aggressive**, slowly growing, nonmetastazing lesions to **highly aggressive**, lethal sarcomas (Sanerkin and Gallagher, 1979; Gitelis et al, 1981). Conventional chondrosarcoma is the most frequent malignant cartilage tumor, and it is further subdivided into three grades based on the level of nuclear atypia. Most chondrosarcomas are of the low and intermediate grades (grades 1 and 2). Since the degree of atypia in grade 1 chondrosarcoma may overlap with the atypia seen in benign chondroma, it is often impossible to differentiate these lesions without clinical and radiographic correlation. The special types of chondrosarcoma include **dedifferentiated**, **clear-cell**, and **mesenchymal chondrosarcoma** (McCarthy and Dorfman, 1982; Frassica et al, 1986; Laporte et al, 1996). These tumors have distinct morphologic features and clinical behaviors, and should be considered entities separate from conventional chondrosarcoma. The differences in the biologic potential of cartilage lesions, as related to their degree of differentiation, are provided in Figure 36-7.

Because of the presence of nuclear atypia in many benign neoplastic and metaplastic conditions that overlaps with atypia seen in malignant cartilage tumors, **aspiration cytology has a limited application in the differential diagnosis of cartilage lesions**. It is typically used as a preliminary diagnostic approach to radiographically identified lesions suspected to represent chondroblastoma, and, less frequently, chondromyxoid fibroma. It may also be used to rule out dedifferentiation in radiographically suspected high-grade chondrosarcoma. Reactive and metaplastic cartilage lesions are practically never diagnosed by cytology. Cytology is **also not recommended as a diagnostic modality for the differential diagnosis of benign versus low to intermediate grade hyaline cartilage tumors**, but it may be used to verify the nature of clinically and radiographically identified recurrent or metastatic lesions in patients with a history of treated chondrosarcoma.

Chondromyxoid Fibroma

Pathology and Histology

Chondromyxoid fibroma is composed of myxoid mesenchymal tissue, corresponding to early primitive phases of

P.1349

cartilaginous differentiation. It accounts for less than 1% of all primary bone tumors (Feldman et al, 1970). Chondromyxoid fibroma has a predilection for metaphyseal parts of the long tubular bones, predominantly of the lower extremity.

Figure 36-7 Differences in the biological potential of cartilage lesions. Graphic representation related to their degree of differentiation and clinical behavior. (From H. Dorfman and B. Czerniak, *Bone Tumors*, Mosby, Inc., St. Louis, 1998.)

Approximately 30% of cases are diagnosed in the knee region, where the proximal tibial metaphysis is the most frequently involved site, followed by the distal femoral metaphysis. A unique subset of chondromyxoid fibromas involves the **small bones of the acral skeleton**, predominantly the feet. The pelvis, especially the ilium, is a frequently affected flat bone. Most patients are in their second or third decade of life, but there are scattered cases involving patients in the later decades of life (Batsakis and Raymond, 1989).

Radiographically, chondromyxoid fibromas are well demarcated eccentric lytic lesions whose long axis parallels the affected bone (Fig. 36-8A,B). The intramedullary margin has characteristic sharply demarcated, scalloped borders with sclerosis.

Grossly, chondromyxoid fibroma presents as a sharply demarcated, firm, gray-white lobulated mass that is eccentrically located and is always surrounded by intact periosteum.

Microscopically, chondromyxoid fibroma shows a pseudolobulated architecture with myxomatous and chondroid areas separated by hypercellular tissue (Fig. 36-9A,B). The hypercellular component is composed of mononuclear cells with scattered multinucleated giant

cells, and shows an overall resemblance to chondroblastoma. Immature myxoid mesenchymal tissue, which creates a pseudolobulated pattern, contains stellate or oval cells that may present some degree of hyperchromasia. Foci of early primitive chondroid differentiation may be present (Bleiweiss and Klein, 1990).

Approximately 30% of chondromyxoid fibromas, especially these located in the small bones of the acral skeleton, show focal features of nuclear atypia. If the microscopic features are analyzed without correlation with clinical and radiologic presentations, they may be misinterpreted as myxoid chondrosarcoma (Wu et al, 1998).

Cytology

Fine-needle aspirates of chondromyxoid fibroma typically show ill-defined lakes of myxoid material with scattered, isolated, primitive mesenchymal cells and occasional multinucleated giant cells (Fig. 36-9C). Less frequently, three-dimensional hypercellular clusters of loosely arranged cells, corresponding to more cellular chondroblastoma-like areas, are present (Fig. 36-9D). In general, a cytologic diagnosis of chondromyxoid fibroma can be established when the microscopic features are correlated with a characteristic radiologic presentation in its typical location. If the chondromyxoid fibroma involves less typical anatomic sites and the radiographic presentation is equivocal, it is usually cytologically diagnosed as an unclassified benign myxoid lesion.

Chondroblastoma

Pathology and Histology

Chondroblastoma is a distinct benign cartilage tumor composed of mononuclear chondroblastic cells that focally produce

P.1350

immature cartilaginous matrix (Dahlin and Ivins, 1972). Chondroblastomas are rare lesions, accounting for only about 1% of all primary bone tumors. They have a predilection for the epiphyses of the major long tubular bones. The distal femoral and proximal tibial epiphyses, followed by the proximal humerus and proximal femur, are the most frequently involved sites. Epiphyseal-equivalent sites of flat bones, such as the periacetabular region in the pelvis, may also be involved. Most chondroblastomas are diagnosed in skeletally immature patients in their second decade of life. Approximately 10% of these lesions are diagnosed in patients older than 50 years (Turcotte et al, 1993a).

Figure 36-8 Chondromyxoid fibroma: radiographic features. Plain radiographs of a large chondromyxoid fibroma of the distal femoral metaphysis. The lesion is completely radiolucent, sharply demarcated by a sclerotic margin, and eccentric in location.

Chondroblastoma may recur after simple curettage, **and may produce benign lung implants** that can be successfully treated by surgery. In extremely rare instances, long-lasting chondroblastomas may progress to a high-grade sarcomatoid malignancy.

Radiographically, chondroblastomas are benign-appearing oval or round lytic lesions located in the epiphysis, with a sharply demarcated sclerotic margin (Fig. 36-10A-D). Larger tumors may expand the bone contour but they do not erode the overlying cortex (Bloem and Mulder, 1985). Approximately 20% of chondroblastomas show superimposed **aneurysmal bone cyst formation**, which typically produces marked expansion of the involved bone. Such lesions may have an aggressive radiographic appearance, with a completely destroyed cortex (Kurt et al, 1990).

Grossly, chondroblastomas are well demarcated, gray-tan lesions that frequently undergo a secondary cystic change.

Microscopically, chondroblastomas are composed of round or oval mononuclear chondroblastic cells with scattered multinucleated giant cells (Fig. 36-11A,B,D). Chondroblastic cells have round or oval dense eosinophilic cytoplasm with eccentrically placed nuclei, which frequently show characteristic longitudinal clefts (grooves). Scattered multinucleated giant cells have features of osteoclasts.

Matrix deposition with myxoid features representing early cartilage formation, and characteristic **focal linear calcifications** (referred to as **chicken wire**) are typical features of chondroblastoma.

The formation of more mature hyaline cartilage is extremely rare. The microscopic features of aneurysmal bone cyst formation can be found in most lesions. Secondary reactive changes, such as fibrosis, foamy histiocytes, and reactive bone formation, are usually seen at the periphery of the lesion.

Cytology

Fine-needle aspirates of chondroblastoma are cellular and contain a population of **mononuclear chondroblasts** admixed with scattered **multinucleated giant cells**. Dispersed mononuclear chondroblasts demonstrate well-defined, deeply eosinophilic cytoplasm with centrally or eccentrically placed oval or round nuclei, which frequently contain longitudinal grooves (Fig. 36-11C-G). Larger, more active chondroblasts show characteristic **clearing of cytoplasm** near the nucleus, which ultrastructurally represents a large Golgi apparatus. Three-dimensional clusters of mononuclear chondroblastic cells are infrequent. **Multinucleated osteoclast-like giant cells**, characterized by multiple dispersed nuclei, are usually present (Fig. 36-11). The multinucleated giant cells are a constant cytologic feature of smears from chondroblastoma. In contrast to giant-cell tumor of bone, however, in which nuclei of both mononuclear and multinucleated giant cells present identical morphologic features, the nuclei of chondroblasts differ morphologically from the smaller nuclei of osteoclast-like giant cells. Fragments of myxoid matrix representing early cartilage may be seen in cytologic preparations. Overall, the cytologic features are very characteristic, and chondroblastoma may be diagnosed with a high degree of accuracy by fine-needle aspiration (FNA) biopsy.

Chondrosarcoma

Pathology and Histology

Chondrosarcoma is a malignant neoplasm derived from cartilage lineage cells. It produces an extracellular matrix that is entirely chondroid in nature.

Foci of secondary enchondral ossification may be present, but they should not be confused with osteoblastic differentiation.

Chondrosarcoma is the **second most frequent primary malignant tumor of bone**, accounting for approximately 25% of all primary bone sarcomas. It primarily affects patients

during the six and seventh decades of life. Chondrosarcomas have a predilection for the trunk bones, which are involved in nearly 50% of the cases, with the pelvis and ribs being the typical sites of involvement (Shives et al, 1989; Sheth et al, 1996; Pring et al, 2001). Long tubular bones, such as the femur and humerus, are next in frequency. Chondrosarcoma extremely rarely affects the small bones of the hands and feet (Ogose et al, 1997; Cawte et al, 1998). The most common sites of skeletal involvement and the peak age incidence are shown in Figure 36-12.

More than 90% of primary chondrosarcomas are conventional intramedullary tumors of bone.

Primary juxtacortical

P.1353

(surface) chondrosarcomas are extremely rare. **Secondary chondrosarcomas** that complicate other conditions, such as osteochondromas, Ollier's disease, or solitary enchondromas, are morphologically very similar to conventional chondrosarcomas. They constitute a distinct group of lesions and are defined by the clinical settings in which they occur. The special types include **dedifferentiated**, **mesenchymal**, and **clear-cell chondrosarcoma** (Frassica et al, 1986; Nakashima et al, 1986; Ishida et al, 1995; Hoang et al, 2000; Estrada et al, 2002). These morphologically distinct tumors have specific clinical and radiologic presentations that should be separated from those of conventional chondrosarcomas (Eustace et al, 1997). Tumors in which malignant cartilaginous cells exhibit bone-forming capability should be classified as chondroblastic osteosarcoma and not as chondrosarcomas (Welkerling et al, 1991).

Figure 36-11 Chondroblastoma: histologic and cytologic features. *A.* Histological section of chondroblastoma showing the typical linear streaks of calcifications (chicken wire calcification) and areas of chondroid deposition (*). *B.* High magnification of chondroblastoma with chondroblastic cells displaying peripherally located nuclei and scattered multinucleated giant cells. *C.* Fine-needle aspirate shows dispersed chondroblastic cells with oval cytoplasm. *D.* Histologic section demonstrating multinucleated giant cells surrounded by mononuclear chondroblastic cells. *E.* Multinucleated giant cell in a fine-needle aspirate. *F,G.* Higher magnification of chondroblastic cells in a fine-needle aspirate. Note the well demarcated oval eosinophilic cytoplasm and slightly elongated nuclei with dispersed chromatin and occasional longitudinal grooves (*arrow*).

Chondrosarcomas range in **behaviors** from slowly growing, nonmetastasizing tumors to highly aggressive lethal sarcomas with a high propensity for distant metastasis. Based on the histological features, such as nuclear atypia and cellularity, conventional chondrosarcoma is subdivided into **three grades**. These grades correlate well with the clinical behavior of the tumor (Sanerkin, 1980). Grade 1 chondrosarcomas are typically indolent, locally aggressive

lesions with minimal or no potential for distant metastasis. Grade 2 tumors are intermediate in their malignant behavior and exhibit low metastatic potential. Most of the conventional chondrosarcomas are low- to intermediate-grade lesions. Only approximately 10% of conventional chondrosarcomas are high-grade (grade 3) tumors, which exhibit aggressive behavior with a high potential for distant metastasis. In general, chondrosarcomas produce distant blood-borne metastases, primarily to the lungs, but occasionally to regional lymph nodes. Pain of several months' duration is a very characteristic clinical symptom and represents an important element in the differential diagnosis between malignant and benign cartilage lesions.

Radiographically, chondrosarcoma presents as an area of radiolucency that frequently contains punctuate and ring-like calcifications (Fig. 36-13A-C). The density of these

P.1354

calcifications and their level of mineralization may vary from lesion to lesion, as well as in different areas of a single lesion. In rare instances, cartilage lesions appear so densely calcified that it may not be possible to distinguish them from bone-forming tumors. On the opposite end of the spectrum are cartilaginous lesions that are radiographically completely lytic. Most frequently, however, chondrosarcoma presents as a radiolucent area with moderate numbers of opacities, and its cartilaginous nature can be easily recognized on plain radiographs. Bone contour in the affected region is usually expanded and the overlying cortex is thinned, showing multiple inner surface erosions (**endosteal scalloping**). In more advanced lesions, complete cortical disruption with an extension into soft tissue is present.

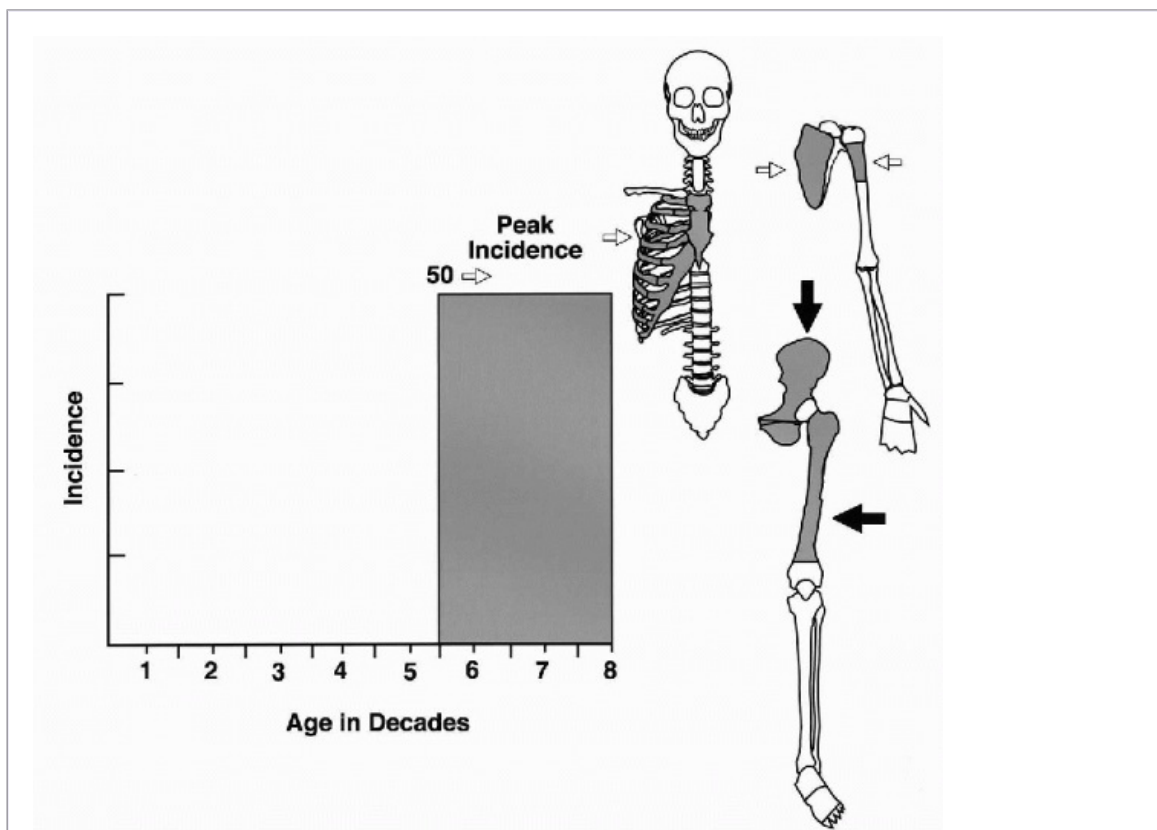

Figure 36-12 Chondrosarcoma: peak age incidence and frequent sites of skeletal involvement. Most frequent sites are indicated by solid black arrow. (From H. Dorfman and B. Czerniak, *Bone Tumors*, Mosby, St. Louis, 1998.)

Grossly, a characteristic picture of chondrosarcoma is that of a lobulated tumor composed of translucent hyaline nodules (Fig. 36-13B-D). Mineralization of the peripheral parts of these lobules produces a chalk-like or granular appearance. The less differentiated tumors may present as soft and myxomatous lesions. Hemorrhage and necrosis are sometimes seen in these lesions.

Microscopically, the cartilaginous nature of the lesion is easy to recognize. The tumor cells resemble normal chondrocytes and lie in the lacunar spaces embedded within hyaline cartilage matrix (Fig. 36-14A). Foci of myxoid change may be present. The lobulated architecture of the lesion is easily appreciated at low power. The tumor cells are more or less uniformly distributed in the cartilaginous matrix, or they form small clusters. Chondrosarcomas show various degrees of cytologic atypia and cellularity, which provide the foundation for their three-tier grading system. In general, grade 1 chondrosarcomas are microscopically very similar to an enchondroma or normal cartilage, and their diagnosis cannot be established without supporting radiologic and clinical evidence. Grade 2 chondrosarcomas are characterized by increased cellularity and obvious nuclear atypia. The cells form loose clusters that vary in size. Nuclei with open chromatin pattern and distinct nucleoli are present in the majority of the cells. Binucleated cells are frequent. All chondrosarcomas with myxoid change are classified as grade 2 tumors. Grade 3 chondrosarcomas are frankly malignant lesions with high cellularity, prominent nuclear atypia, and mitotic figures (Pring et al, 2001).

Cytology

Aspiration biopsy rarely has any value in the differential diagnosis of borderline cartilage lesions, and is practically never performed when there is a problem in differentiating enchondroma from low-grade chondrosarcoma. Aspirates are often performed in radiologically aggressive lesions to confirm their cartilaginous nature and rule out potential progression to an undifferentiated, high-grade sarcomatoid neoplasm (dedifferentiation). Cytology is also used in the differential diagnosis of enlarged lymph nodes and other internal organ lesions to rule out metastasis or recurrence of clinically known chondrosarcoma. Therefore, the description of cytologic features is restricted to grade 2 and higher lesions, as well as dedifferentiated chondrosarcoma.

Aspirates from chondrosarcoma are moderately to highly cellular and contain **neoplastic cells arranged in loose three-dimensional clusters**, dispersed within an amorphous myxoid or hyalinized eosinophilic background, corresponding to cartilage matrix (Fig. 36-14B,C). Cartilage tumor cells are large, oval, with well demarcated, dense eosinophilic cytoplasm (Fig. 36-14D-H). Myxoid chondrosarcoma of bone has unique cytologic features showing **clusters of poorly differentiated mesenchymal cells with**

P.1355

numerous blood vessels, corresponding to plexiform vascular channels seen in histologic specimens. Aspirates from conventional grade 2 and 3 chondrosarcoma show obvious features of cell pleomorphism with prominent nucleoli. Their cartilaginous nature usually can be recognized in correlation with clinical and radiologic features. Large intranuclear cytoplasmic inclusions ("nuclear holes") may be present (Fig. 36-14E). As in histologic preparations, tumor cells in aspirates are positive for S-100 and Sox-9 nuclear protein (Wehrli et al, 2003). Diffusely **myxoid chondrosarcomas of bone** are less likely to be cytologically recognized and are often designated as unclassified myxoid neoplasms. The cytologic features of dedifferentiated chondrosarcoma are indistinguishable from any high-grade undifferentiated sarcoma or

malignant fibrous histiocytoma. Dedifferentiated chondrosarcoma can be recognized cytologically if the microscopic features correlate with radiologic and clinical presentations showing biphasic bone tumor composed of cartilage and associated with highly aggressive, noncartilaginous areas. The cytologic features of metastatic chondrosarcoma reflect those of the primary tumor.

Figure 36-13 Chondrosarcoma: radiographic and gross features. *A.* Plain radiograph showing a destructive intramedullary lesion involving the distal femur with irregular thickening of the overlying cortex, and complete cortical disruption laterally. *B.* T₁-weighted MR image of the same tumor, showing an extensive low-signal intramedullary lesion with cortical disruption and soft-tissue extension laterally. *C.* T₂-weighted image of the same tumor shows irregular signal enhancement within the lesional tissue, with complete cortical disruption and soft-tissue extension laterally. *D.* Gross specimen of the same lesion, showing extensive intramedullary cartilaginous tumor with a destructive growth pattern and irregular thickening of the overlying cortex, with complete cortical destruction and soft-tissue extension laterally.

GIANT-CELL TUMOR

Pathology and Histology

Giant-cell tumor of bone is a distinct clinicopathologic entity characterized by locally aggressive growth of the tumor.

P.1356

It is composed of **mononuclear cells, resembling macrophages, intermingled with a prominent population of multinucleated giant cells**. Giant-cell tumors of bone account for approximately 4% of all primary bone tumors.

Figure 36-14 Chondrosarcoma: histologic and cytologic features. *A* Histologic features of conventional chondrosarcoma showing a hyaline tumor with cartilage tumor cells residing in lacunar spaces, and displaying mild to moderate variations in size consistent with grade 2 chondrosarcoma. *B, C*. Fine-needle aspirates show loosely arranged tumor cartilage cells surrounded by hyaline cartilage matrix. Note the open chromatin of the nuclei with prominent nucleoli. Some of the cartilage tumor cells show double nuclei. *D, E*. Higher magnification to show loosely arranged cartilage tumor cells

with oval cytoplasm and nuclei with prominent nucleoli and occasional intranuclear cytoplasmic inclusions (*arrows*). *F-H*. Higher magnification of individual chondrosarcoma cells with oval cytoplasm and peripherally located nuclei showing prominent nucleoli and intranuclear cytoplasmic inclusions (*arrow*).

The epiphyseal ends of long tubular bones, such as the distal femur, proximal tibia, and distal radius, are the most frequently involved sites. The sacrum is the most frequently involved bone in the axial skeleton (Turcotte et al, 1993b). Giant-cell tumors of bone are virtually always encountered in skeletally mature patients.

The peak age incidence is in the third or fourth decades of life. It is very unusual for giant-cell tumors to occur in patients younger than 20 years or older than 55 years (Fig. 36-15).

Giant-cell tumors of bone are locally aggressive neoplasms with very limited potential for distant metastasis (Frassica et al, 1993). Rarely, giant-cell tumors may behave more aggressively, producing **pulmonary implants**. Typically, pulmonary implants of conventional giant-cell tumors are solitary lesions characterized by a very slow growth rate and a nonaggressive clinical course. Occasionally, however, they present as multiple miliary-type lesions that may follow an aggressive clinical course (Siebenrock et al, 1998).

Development of high-grade sarcoma (dedifferentiation) with features of malignant fibrous histiocytoma or osteosarcoma in previously conventional giant-cell tumor is a well-established phenomenon. This usually occurs after several recurrences of conventional giant-cell tumor, and is more often seen after irradiation of the primary lesion. Primary (de novo) malignant giant-cell tumor is extremely rare (Meis et al, 1989).

The primary treatment for conventional giant-cell tumor is curettage and bone grafting. Recurrent lesions usually are adequately treated by a second curettage.

Giant-cell tumor has a very **characteristic radiologic appearance** and typically presents a well-defined, eccentric lytic lesion that involves the epiphysis of a skeletally mature patient. The bone contour is expanded and shows a thinned cortex, which sometimes may be focally destroyed (Fig. 36-16A). Radiologic features of aggressiveness, such as ill-defined margins; a thinned, expanded cortex; invasion of the cortex; and extension of the lesion into surrounding soft

P.1357

tissue do not correlate with microscopic criteria of malignancy or the clinical behavior of the tumor.

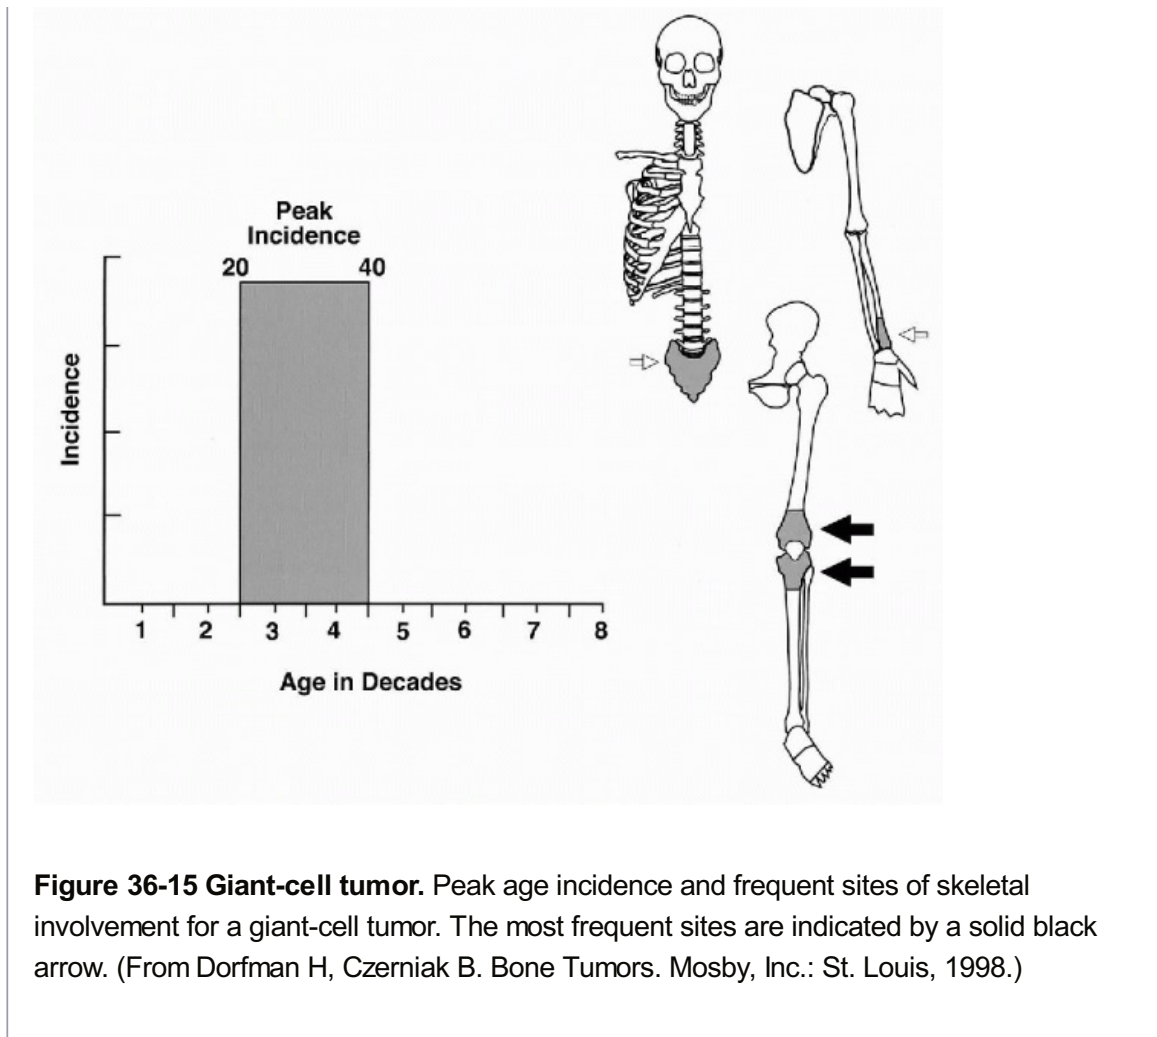

Figure 36-15 Giant-cell tumor. Peak age incidence and frequent sites of skeletal involvement for a giant-cell tumor. The most frequent sites are indicated by a solid black arrow. (From Dorfman H, Czerniak B. Bone Tumors. Mosby, Inc.: St. Louis, 1998.)

Grossly, the soft, friable, fleshy, red-brown tumor tissue is well demarcated from the surrounding bone and soft tissue. Areas of hemorrhage, necrosis, and cyst formation are constant gross features. A thin layer of fibrous tissue and reactive bone usually delineates the tumor. When bony cortex is destroyed and the tumor extends to the soft tissue, a thin shell of subperiosteal bone surrounds the periphery of the lesion (Fig. 36-16B).

Histologically, the two populations of cells (mononuclear histiocytic cells and multinucleated giant osteoclastlike cells) are readily recognized (Fig. 36-16C,D). **Mononuclear cells** are oval, plump, or spindle-shaped, and are the predominant components of the lesion, whereas multinucleated giant cells are uniformly scattered throughout the tumor. The **giant cells** usually have a large number of nuclei, which cluster centrally within the cytoplasm. Not infrequently, more than 100 nuclei can be found in one such cell. The nuclei of the multinucleated giant cells and the mononuclear cells are identical. The microscopic features of giant-cell tumor are frequently modified by secondary changes. Focal proliferation of fibroblasts, hemorrhage, necrosis, and aneurysmal bone cyst formation are frequently seen. In some instances, these changes may almost totally obscure the features of the preexisting neoplasm. In such cases, it is extremely difficult to diagnose giant-cell tumor without careful examination of the clinical and radiologic data.

Cytology

Fine-needle aspirates of giant-cell tumor typically show two populations of cells: the dominant mononuclear cells and the less frequent multinucleated giant cells (Fig. 36-16E-G).

Mononuclear cells, which have a histiocytoid appearance, are either dispersed or arranged in small three-dimensional clusters (Fig. 36-16D-F). Multinucleated giant cells are similar to osteoclasts but usually contain many more nuclei. Characteristically, **the nuclei of mononuclear cells are identical to the nuclei of giant cells**. This is a distinct cytologic feature of giant-cell tumor of bone. These cytologic features are often obscured by **secondary changes**, such as proliferation of fibrous tissue accompanied by foamy histiocytes. In such instances, correlating the cytologic findings with the clinical and radiologic data may help to establish the correct diagnosis.

CHORDOMA

Pathology and Histology

Chordoma is a malignant neoplasm that exhibits notochordal differentiation and clinically is predominantly characterized by locally aggressive growth.

It accounts for 3% to 4% of all primary malignant bone tumors, and is the fourth most frequent primary malignant tumor of bone after osteosarcoma, chondrosarcoma, and Ewing's sarcoma. Chordoma almost exclusively involves the axial skeleton. **The base of the skull and the sacrococcygeal region are the most frequently affected sites**, accounting for nearly 90% of all cases. Rarely, chordoma may involve vertebral bodies, mainly in the lower thoracic and lumbar region. Extraskelatal soft-tissue chordomas may originate from the paraspinal soft tissue. The incidence gradually increases during the fifth and six decades of life.

Chondroid chordoma is a rare variant of chordoma

P.1358

characterized by the presence of **cartilaginous elements intermingled with conventional chordoma**. Various proportions of chondroid and chordoid tissue may be present in different lesions (Mitchell et al, 1993; Ishida and Dorfman, 1994).

Figure 36-16 Giant-cell tumor of proximal tibial epiphysis. *A.* Anteroposterior view of a giant-cell tumor in a plain radiograph involving the proximal tibial epiphysis. Note the expanded contour of the tibia. *B.* Gross photograph of the resection specimen shown in *A* with an expansile red-brown tumor containing fine yellowish septations. The cortex overlying the tumor is destroyed with expansion of the bone contour delineated by a thin fibrous capsule. *C.* High magnification showing two multinucleated giant cells within mononuclear stroma. Note that the nuclei of the mononuclear stromal cells and the multinucleated giant cells have a similar appearance. *D.* Histologic appearance of the same tumor showing scattered multinucleated giant cells among mononuclear stromal cells resembling histiocytes. *E, F.* Fine-needle aspirates containing multiple mononuclear stromal cells and multinucleated osteoclastic cells. *G.* Higher power demonstrating mononuclear stromal cells with oval nuclei and discrete nucleoli. *Inset.* A stromal cell with two nuclei and oval densely eosinophilic cytoplasm.

Progression to a high-grade undifferentiated sarcoma (dedifferentiation), similar to that seen in chondrosarcoma, may occur in chordoma. In dedifferentiated tumors, conventional chordoma is accompanied by high-grade malignant spindle cells, reminiscent of a pleomorphic sarcoma (Meis et al, 1987; Tomlinson et al, 1992).

Although chordoma behaves mainly as a locally aggressive tumor, it is associated with a high mortality rate (the mean survival is approximately 4 years). This is because of its location in the axial skeleton and the frequent involvement of vital structures. **Distant metastases are rare**

and occur in less than 10% of patients. Complete surgical excision of the primary tumor is a treatment of choice. Unresectable

P.1359

tumors are treated by debulking and adjuvant radiation therapy. Aggressive clinical behavior with early distant metastases and massive vascular tumor emboli may occasionally be seen.

Pain and symptoms originating from compression of neighboring organs and structures are the characteristic clinical presentations.

Radiographically, chordomas are lytic lesions with scattered discrete opacities, which represent intralesional calcifications (Fig. 36-17A,B). The involvement and destruction of neighboring organs, such as the clivus, sella turcica, optic nerve, pituitary gland, vertebral bodies, spinal cord, sacrum, and rectum, occur very frequently.

Grossly, chordomas are similar to chondrosarcomas and present as soft, gray-tan multilobulated masses (Fig. 36-17C). They are well demarcated lesions, but the neoplastic tissue usually extends beyond grossly recognizable borders.

Figure 36-17 Chordoma: radiographic, gross, and microscopic features. *A.* Axial computer tomogram shows a destructive mass protruding posteriorly and anteriorly from the sacrum. *B.* T1-weighted sagittal MR image of chordoma shown in *A* with a predominantly anterior low signal mass (*arrows*). *C.* Sagittally cut resection specimen of the tumor shown in *A* and *B* demonstrates a lobulated fleshy tumor mass destroying the sacrum and extending to the soft tissue anteriorly and posteriorly. *D.* Histologic section of the same tumor shows cords of chordoma cells with multivesicular cytoplasm growing in a myxoid stroma.

Microscopically, chordomas are composed of cords, nests, and solid areas of large cells embedded in myxoid intercellular matrix (Fig. 36-17D). The proportions of the cellular matrix and its components vary among cases and in different parts of the same tumor. In the most typical tumors, areas of neoplastic cells form anastomosing cords with focal solid areas separated by the matrix. **Vacuolization of the cytoplasm** of chordoma cells is a characteristic cytologic feature (Fig. 36-18A). Large single or multiple vacuoles, which displace the nucleus peripherally, create a morphology similar to that of a signet ring cell. A **physaliphorous cell** containing centrally located nucleus, scalloped by multiple cytoplasmic vacuoles, is a hallmark

P.1360

of chordoma (Fig. 36-18B). The **immunohistochemical profile** of chordoma, which is characterized by the co-expression of S-100 protein and epithelial markers (e.g., cytokeratins and epithelial membrane antigen (EMA)), is helpful in establishing a differential diagnosis with chondrosarcoma. Positive cytoplasmic staining with periodic acid-Schiff, which is diastase sensitive, is also very characteristic.

Figure 36-18 Chordoma: histologic and cytologic features. *A,B.* Histologic features of chordoma demonstrating tumor cells with vacuolated cytoplasm growing in cords and trabeculae within loose myxoid stroma. A larger tumor cell with vacuolated cytoplasm surrounding the nucleus (physaliphorous cell) is shown in *B* (arrows). *C.* Fine-needle aspirate containing loosely arranged chordoma cells with myxoid extracellular matrix. *D.* Higher magnification of chordoma cells with ill-defined cytoplasm, and a larger cell with a prominent vacuolated cytoplasm corresponding to a physaliphorous cell (arrows). *Inset.* Higher magnification of chordoma cells with vesicular cytoplasm and prominent nucleoli.

Cytology

Fine-needle aspirates from chordoma usually are cellular and contain abundant myxoid material admixed with clear, vacuolated neoplastic cells (Fig. 36-18C,D). The presence of cells with vacuolated cytoplasm and centrally placed, scalloped nuclei (i.e., **physaliphorous cells**) is characteristic of chordoma (see Fig. 36-17). However, such classic cells are rare. The vast majority of the tumor cells show dense eosinophilic cytoplasm or are lipoblast-like with single or

several larger cytoplasmic vacuoles displacing the nucleus peripherally. Tumors predominantly **composed of cells mimicking adipose tissue are referred to as lipoma-like chordomas.** The cytologic features, combined with classic radiologic and clinical presentations, allow for correct cytologic diagnoses to be established in most cases (Kay et al, 2003). The immunohistochemical

P.1361

features, such as coexpression of epithelial markers and S-100 protein, can be also tested in cytological preparations.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst is a rare, multiloculated, benign cystic lesion that almost always arises in bone but may occur as a secondary phenomenon in soft-tissue lesions. The term “aneurysmal bone cyst” was introduced by Jaffe (1956) and Lichtenstein (1956) to describe a blow-out distention of the affected bone by a multiloculated cystic lesion filled with blood. The process is locally destructive and has a high propensity for recurrence. The age incidence peak occurs during the second decade of life. Aneurysmal bone cyst may affect any bone and has an almost uniform skeletal distribution. **Microscopically, blood-filled cysts of various sizes** are bordered by **septa created by fibroconnective tissue; prominent giant-cell reaction and focal reactive bone formation** are also evident. Aneurysmal bone cyst, as a secondary phenomenon, may occur with either benign or malignant lesions. The major precursor conditions, in order of their frequency for an aneurysmal bone cyst, are listed in Table 36-2.

The most characteristic **radiographic feature** is a blow-out distention of the periosteum outlined by the thin shell of a subperiosteal bone.

Cytology is very rarely used in the differential diagnosis of such lesions, in part because the cytologic presentations of telangiectatic osteosarcoma and benign aneurysmal bone cyst may be similar. In typical cases, aspirates from benign aneurysmal bone cyst are bloody and contain dispersed fragments of fibroconnective tissue, as well as scattered isolated histiocytic cells with multinucleated giant osteoclasts. Mitotic figures and nuclear pleomorphism with hyperchromasia can be seen in benign lesions, but frank cancer cells and atypical mitoses are absent.

EWING'S SARCOMA AND PRIMITIVE NEUROECTODERMAL TUMORS

Pathology and Histology

In the early 1920s James Ewing identified a **distinct round-cell tumor** that predominantly affects the **long tubular bones of young patients** in the absence of a lymphoma/leukemia clinical picture. He called this type of lesion “diffuse endothelioma” of bone, and separated it from the general category of unclassified round cell sarcomas and lymphoproliferative disorders. The consistent presence of a **specific chromosomal abnormality** (i.e., the reciprocal translocation of chromosomes 11 and 22 t(11;22)(q24;q12)) is a characteristic finding (see below). Ewing's sarcoma and its related conditions serve as a prototype for the contemporary diagnostic approach in which molecular data contribute to the diagnosis.

Other similar lesions, which occur mainly in young patients but have anatomic and microscopic features distinct from those of classic Ewing's sarcoma, are described as **primitive neuroectodermal tumors (PNETs) and Askin's tumor**. They have been linked to Ewing's sarcoma by the same chromosomal translocation, which is a consistent finding in these lesions. The same genetic abnormality has also been identified in at least some of the tumors classified as **small-cell osteosarcoma** (see discussion below). At the time of this writing, Ewing's sarcoma is considered the prototype tumor of this group, while PNETs represent a variety of closely related lesions distinguished on the basis of an arbitrarily defined degree of neural differentiation. Askin's tumor represents either classic Ewing's sarcoma or PNET affecting the thoracopulmonary region.

Ewing's sarcoma is a distinct, highly aggressive sarcoma of bone that occurs predominantly in the long tubular bones of the extremities but also may affect the pelvis, ribs, and other bones (Wilkins et al, 1986). Approximately 40% of these lesions originate in the deep soft tissue of the

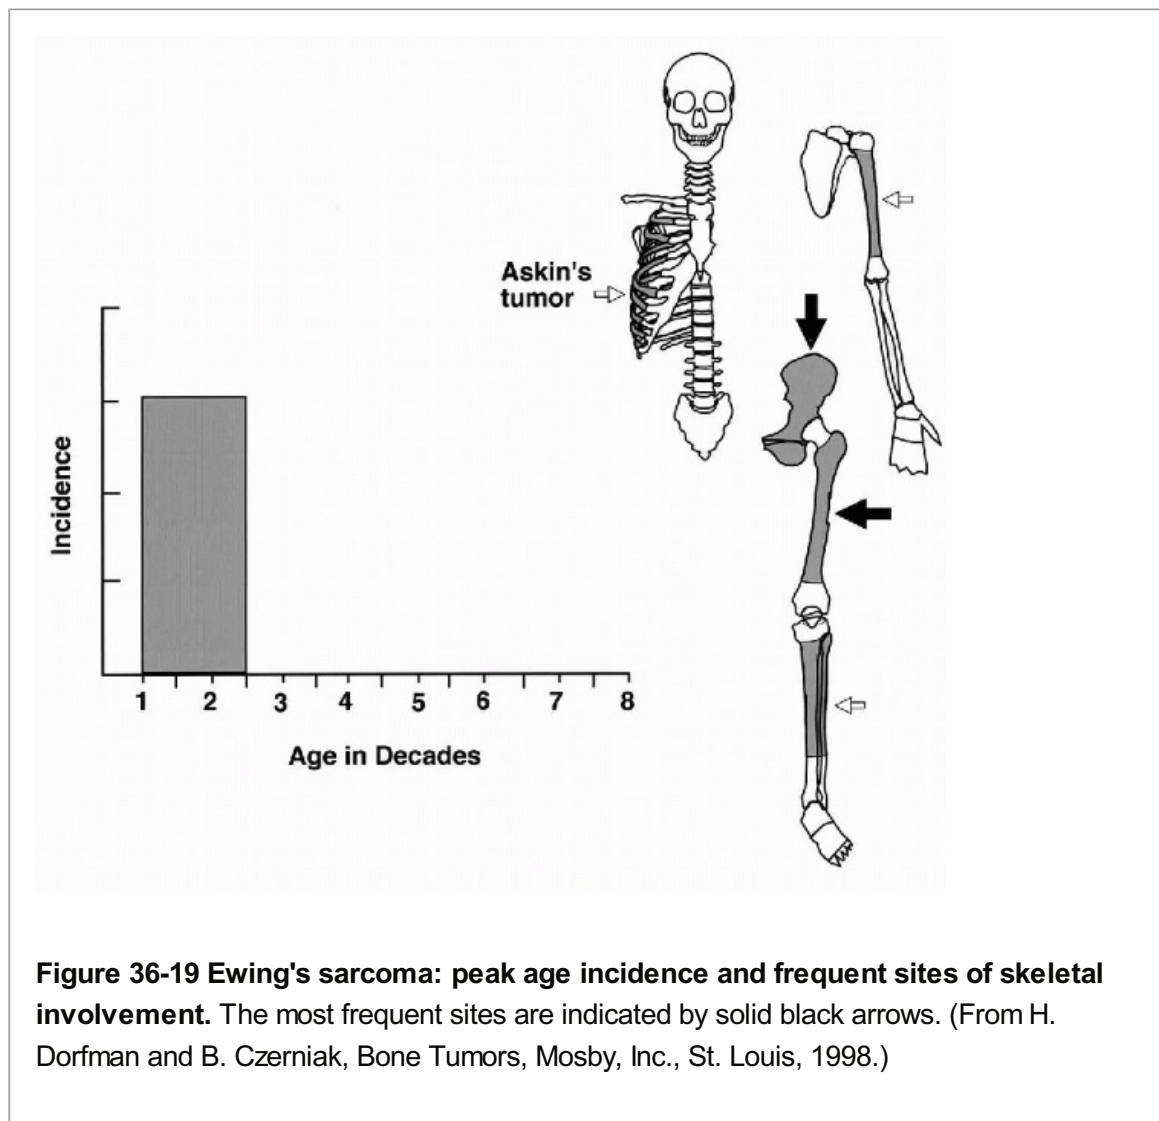

limbs. Ewing's sarcoma accounts for 6% to 8% of all malignant tumors of bone, and the age incidence peaks during the second decade of life (Fig. 36-19).

Males are affected more frequently than females, at a ratio of approximately 1.5:1. This tumor is extremely rare in patients older than 30 years, and practically never occurs in African Americans. Rare examples of Ewing's sarcoma have been described in parenchymal organs and subcutaneous tissue.

Ewing's sarcoma has a high propensity for distant metastases, primarily to the lungs, and nearly 50% of the patients present with disseminated disease. Multimodality treatment, consisting of irradiation, chemotherapy, and surgery has significantly improved prognosis in comparison with

P.1362

the prechemotherapy era. Still, even with modern treatment the overall 5-year survival of patients with a disseminated disease is only about 30%.

Mild fever and localized swelling around the tumor are the most frequent clinical symptoms. The clinical picture may simulate an inflammatory process, such as osteomyelitis.

Radiologically, Ewing's sarcoma presents as an ill-defined, destructive intramedullary lesion typically involving the diaphyses of the long tubular bones. A permeative or **"moth-eaten" pattern, accompanied by a prominent multilayered periosteal reaction (onion skin), is characteristic** (Fig. 36-20A). The cortex of the affected bone may exhibit diffuse sclerosis and

thickening. A concave defect on the bone surface, referred to as **saucerization**, is seen in lesions in which a subperiosteal and soft-tissue mass compresses the outer surface of the cortex.

Grossly, Ewing's sarcoma involves large segments of the medullary cavity (Fig. 36-20B). Small nests of the tumor permeate the cortex to form a subperiosteal and soft-tissue mass. Frequently, the extraosseous soft-tissue mass is larger than the intraosseous component. The involvement of the medullary cavity is usually more extensive than is apparent from the plain radiograph.

Microscopically, Ewing's sarcoma is composed of **small, round, primitive mesenchymal cells**. Tumor cells have rounded, centrally located nuclei with an indistinct rim of cytoplasm (Fig. 36-20C). The nuclear chromatin is finely granular, with one to three clearly identifiable small- to medium-sized nucleoli. These undifferentiated cells form solid, densely packed sheets that fill the intertrabecular spaces and permeate the cortical Haversian channels. Occasional rosette-like structures may be present. Several types of rosettes can be identified in Ewing's sarcoma. The most frequent is a circular arrangement of cells with processes that form a fibrillar material within the center of the structure (Fig. 36-20C, inset). **These rosettes are identical to those seen in neuroblastoma**. A less mature rosette-like arrangement may be formed by cells in a circular arrangement around an amorphous core. These immature/primitive rosettes should not be used as microscopic evidence of neural differentiation. Flexner-Wintersteiner rosettes, which have a sharply delineated lumen similar to that observed in ependymoma or retinoblastoma, are exceptionally rare in Ewing's sarcoma/PNET. Necrosis, which is frequent, evolves from small patchy foci to large irregular geographic areas. **Apoptosis** is often seen in Ewing's sarcoma. Areas of the tumor with cord or clusters of dark apoptotic cells may simulate a biphasic pattern.

Ewing's sarcoma and PNET show a wide range of neural differentiation. On the one end of the spectrum are Ewing's sarcomas, which are completely negative for any neural markers. On the other end of the spectrum are PNETs, which show obvious microscopic, immunohistochemical, and ultrastructural features of neural differentiation. In general, **two obvious features of neural differentiation are required to classify a lesion as PNET**.

Immunohistochemically, 90% of Ewing's sarcoma/PNET shows expression of MIC2 gene product and vimentin. Positive staining with markers, such as neuron-specific enolase (NSE), Leu7, HNK-1, neurofilaments, glial fibrillary acid protein, chromogranins, and S-100, indicates neural differentiation. It is generally accepted that the most reliable way to identify PNET is to ultrastructurally identify the

P.1363

presence of neurosecretory granules and the formation of axonal cytoplasmic projections (Fig. 36-21).

Figure 36-20 Ewing's sarcoma of the humeral diaphysis. *A.* Plain radiograph shows destructive lytic intramedullary lesion with ill-defined margins and a soft-tissue extension shadow. *B.* Bisected resection specimen showing an extensive intramedullary tumor with permeation of cortex and circumferential extension into soft tissue. *C.* Histologic appearance of Ewing's sarcoma showing primitive undifferentiated mesenchymal cells forming solid areas. *Inset.* A rosette-like structure formed by a circumferential arrangement of tumor cells around a central core containing delicate fibrillar cytoplasmic material. *D-H.* High magnification shows fine-needle aspirates containing undifferentiated round cells, some of which have nucleoli and indistinct cytoplasm that occasionally form rosette-like structures (arrows).

The translocation (11:22)(q24;q12) can be identified in nearly 90% of patients with Ewing's sarcoma/PNET (Aurias et al, 1984; Delattre et al, 1994; Pellin et al, 1994; Lopez-Terrada, 1996). In a small fraction of these tumors, alternative chromosomal translocations can be identified (Sorensen et al, 1994) (Table 36-3). The reciprocal translocation of chromosomes 11 and 22, which involves bands (q24;q12) in Ewing's sarcoma/PNET, represents a prototypic

chromosomal abnormality found in soft-tissue and bone tumors (Fig. 36-22). An initial molecular analysis showed that the chromosome 22 breakpoint is located within the EWS gene, whereas the chromosome 11 breakpoint is located within the FLI-1 gene (Aurias et al, 1984). The reciprocal translocations between two chromosomes create a **new chimeric protein**, which consists of portions of the EWS and FLI-1 proteins (Bhagirath et al, 1995). The EWS gene, located within the (q12) band of chromosome 22, is also involved in all alternative translocations seen in Ewing's sarcoma and PNET, as well as in desmoplastic small round tumor, clear-cell sarcoma, and extraskeletal myxoid chondrosarcoma (Biegel et al, 1993; Sorensen et al, 1994).

The second component in the fusion is the human homologue of the murine FLI-1 gene located on chromosome 11q24 (Baud et al, 1991; Prasad et al, 1992). In the chimeric protein, the RNA-binding domain of the EWS product is substituted for the DNA-binding domain of the FLI-1 gene. In the chimeric EWS-FLI-1 gene, the FLI-1 binding domain is transcribed under control of the EWS promoter. Both partners of the fusion are ubiquitously expressed in human tissues. The molecular structure of the breakpoints associated with the (11;22)(q24;q12) translocation is graphically shown in Figure 36-22.

P.1364

Figure 36-21 Peripheral neuroectodermal tumor (PNET) of bone: ultrastructural features. *A.* Tumor cells with sparse cytoplasmic organelles as seen on low power (×1,500). *Inset.* Histologic appearance of primitive undifferentiated tumor cells. *B.* Tumor cell with washed out glycogen pools (×6,000). *C,D.* Neurosecretory granules (×9,000). *E.* Neurotubules within a cytoplasmic process of a tumor cell (×12,000). *F.* Axonal differentiation of tumor cell with formation of interconnecting cytoplasmic processes (×12,000). *G.* Neurosecretory granules within interdigitating axonal processes (×6,000).

Expression of the MIC2 gene is not specific for Ewing's sarcoma/PNET because it is also expressed in a wide range of unrelated tumors.

Cytology

Aspirates from Ewing's sarcoma/PNET are usually very cellular and contain a population of **dispersed, small, undifferentiated tumor cells** (see Fig. 36-20D-H). A delicate, finely granular chromatin pattern and clearly identifiable small to medium size nucleoli are characteristic. The cytoplasm is indistinct and forms only a narrow rim around the nucleus. Cell clustering and **rosette formation** may occur (see Fig. 36-20D,H). Aspirates from Ewing's sarcoma are important in the diagnostic workup (Akerman et al, 1988; Brahmi et al, 2001). It is often easier to evaluate the morphologic

P.1365

features of cells, especially the details of the nuclei, on cytologic preparations than in small biopsy specimens. Therefore, FNA is used as the initial diagnostic approach when Ewing's sarcoma is clinically suspected. Immunohistochemical and molecular studies for differential diagnoses with other small-cell malignancies may be performed on material obtained for studies (Akhtar et al, 1985b; Akerman et al, 1996; Collins et al, 1998a; Frostad et al, 2002). Overall, Ewing's sarcoma/PNET represents a primary bone sarcoma that can be definitively diagnosed by aspiration cytology in most cases (Akhtar et al, 1985a).

TABLE 36-3 ALTERNATIVE CHROMOSOMAL TRANSLOCATION IN EWING'S SARCOMA AND PNET

Tumor type	Cytogenetics	Genes involved
ES/PNET	t(11;22) (q24;q12)	FLI-1-EWS
	t(21;22) (q22;q12)	ERG-EWS
	t(7;22) (p22;q12)	ETV1-EWS

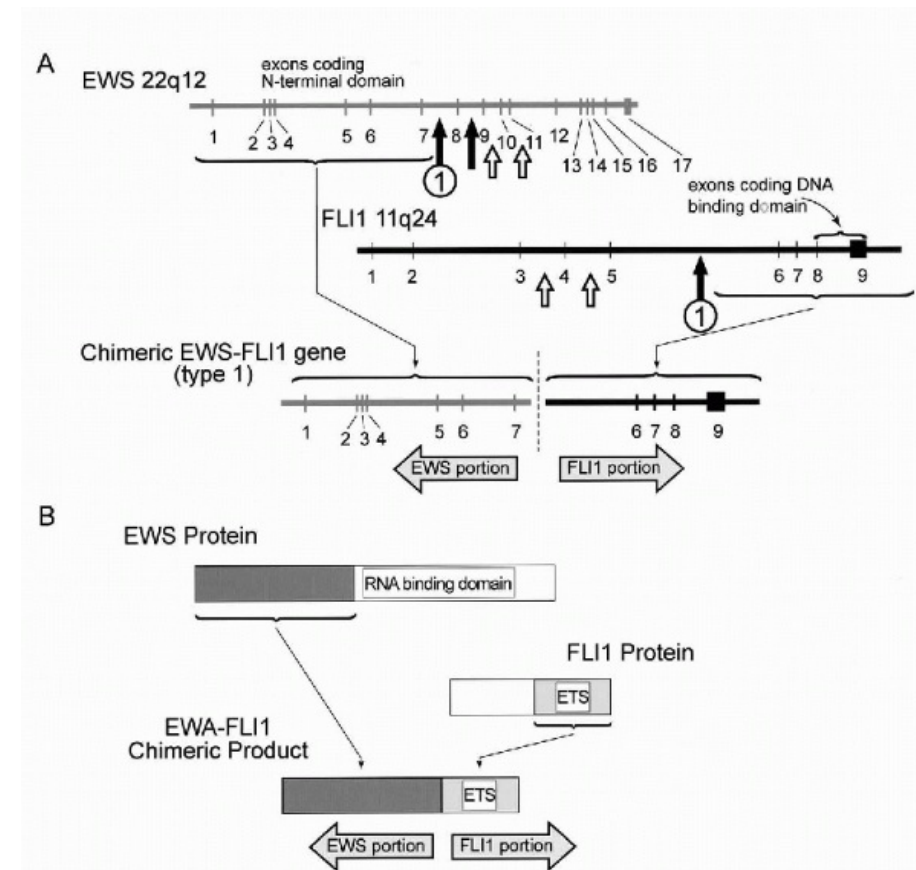

Figure 36-22 Molecular structure of breakpoints associated with t(11;22)(24q;q12) in Ewing sarcoma/PNET. *A.* Exon-intron structures of EWS and FLI-1 genes are shown. Large solid arrows indicate most frequent locations of breakpoints within introns. Molecular structure of one of the most frequent (type 1) chimeric genes, which includes coding sequences for the N-terminal domain of the EWS gene and DNA-binding domain of the FLI-1 gene is also shown. *B.* Schematic representation of the functional domains of the EWS-FLI-1 chimeric product. In the chimeric protein the RNA binding domain of the EWS product is substituted for the DNA binding domain (ETS) of the FLI-1 gene.

METASTATIC TUMORS TO BONE

General Features of Bone Metastases

Metastatic tumors to bone are a more common target of needle aspiration biopsies than primary tumors. The skeleton, with its rich vascular system, is one of the most common sites of the metastatic deposits that usually indicate the presence of disseminated, multisystem disease (which, however, is not necessarily rapidly fatal). The optimum treatment of such metastases depends greatly on the origin and type of cancer involved. Although in most such instances the metastases are linked to a known primary tumor, this is not always the case. Over the years, we have observed many patients in whom bone metastases were the **first manifestation of cancer** of unknown origin. Further, even in the presence of a known primary tumor, the origin of the metastases must sometimes be confirmed. Both of these challenging issues may be occasionally resolved in the aspirated cell samples. Bone metastases occur in **two essential forms: osteolytic (bone resorptive) and osteoblastic (boneforming).**

The mechanism of bone metastases has been the subject of many papers and speculations (Sanerkin, 1980; Autzen et al, 1998; Sanchez-Sweatman et al, 1998; Smit et al, 1998). Clearly, very complex molecular mechanisms must be in place for a tumor to settle in the bone and interact with it.

P.1366

Recently, Roodman (2004) summarized the existing knowledge on this subject, particularly in reference to the differences in the mechanisms of formation of osteoclastic vs. osteoplastic metastases. The interaction between tumor cells (some of which secrete factors that enhance the growth of bone-forming osteoblasts, and some of which stimulate bone-resorbing osteoclasts) are very complex. Prostatic carcinoma is an example of a tumor that secretes factors that stimulate bone growth and lead to frequent osteoblastic metastases (Carlinfante et al, 2003; Cooper et al, 2003).

Radiographically, metastatic tumor in bone presents as destructive foci that may show a wide spectrum of lytic and sclerotic changes. One end of this spectrum is represented by a completely lytic lesion with no discernable bone sclerosis. On the other end is a metastatic deposit that has a marked osteoblastic reaction and appears as a completely sclerotic focus. Most frequently, however, metastatic tumors show a combination of lytic and sclerotic areas.

Since primary bone tumors are very rarely multifocal, the involvement of several skeletal sites is a hallmark of disseminated metastatic disease. Bones of the axial skeleton and proximal portions of the appendicular skeleton are most frequently involved. Parts of the skeleton that are distal to the elbow and knee joints and the mandible are unusual sites of metastases.

Acral metastases involving the small bones of the hands and feet are very rare. Carcinoma of the lung is the most common source of such metastases, although they may also occur with other highly aggressive malignant neoplasms of various origins. Occasionally, metastatic carcinoma may present as a single focus. Kidney, lung, breast, pancreas, thyroid, and colon cancers are the most frequent neoplasms that may produce a solitary metastasis. Sometimes a single metastatic focus may be present without any known primary site.

The clinical symptoms associated with metastatic deposits, such as tenderness, swelling, and pain at the affected site, may precede radiographically detectable changes for several weeks or even months. **Fractures** of bones may be the first manifestation of metastases.

Common Metastatic Tumors to the Skeleton

Lung Carcinomas

Both non-small-cell and small-cell lung carcinomas have a high propensity for metastasizing to the skeleton. Bone metastases have been documented in over 50% of patients with lung cancer (Ihde et al, 1979). Lung cancer typically produces lytic metastatic foci. It is also the most frequent human malignancy that may present as a solitary bone metastasis (Paul et al, 1969; Pazzaglia et al, 1989; Kagohashi et al, 2003). Characteristically, metastatic lung cancer frequently involves unusual sites, such as the acral skeleton, as well as intracortical or subperiosteal sites (Gerlach et al, 1982; Delgadillo and Nichols, 1998; Galmarini et al, 1998).

Cytology

Aspirates from **non-small-cell metastatic lung cancer** are highly cellular and contain large epithelial cancer cells with pronounced atypia (Fig. 36-23A,B). Keratinization and extensive necrosis are frequently seen. Dispersed cells with scanty cytoplasm, which occasionally form

small three-dimensional clusters, characterize metastatic small-cell carcinoma. The nuclei of these cells have coarsely granular chromatin with a few larger chromocenters and no visible nucleoli. Positive immunohistochemical staining for thyroid-transforming factor-1 (TTF1) can be helpful in establishing the origin of metastasis from the lung (Reis-Filho et al, 2000). **Small-cell carcinomas** typically show neuroendocrine differentiation and are positive for a wide range of neuroendocrine markers (see Chapter 20).

Gastrointestinal Carcinomas

Carcinomas of the upper gastrointestinal tract are much more prone to produce bone metastases than cancers of the colon and rectum. In 45% of patients with stomach cancer, a radioscopic scan of the skeleton reveals abnormal uptake (Thomas and Sobin, 1995). The sites affected by metastatic stomach cancer are similar to those affected by other common cancers, and include the spine, ribs, pelvis, femur, and skull. Occasionally, skeletal metastasis is the first presenting symptom in patients with gastric carcinoma, particularly that of the poorly differentiated type (Mohandas et al, 1993). The incidence of bone metastases in colorectal cancer is much lower than in gastric cancer, and is reported to be approximately 23% by autopsy (Baker et al, 1974). Poorly differentiated carcinoma and signet ring cell carcinoma of the colon are more prone to metastasize to bone than well to moderately-differentiated adenocarcinomas. In fact, colon carcinoma is the most frequent gastrointestinal cancer in which solitary skeletal metastasis may appear as the initial clinical event (Hoehn et al, 1979; Choi et al, 1995). However, in such patients, bone metastases usually coexists with metastases to the lung and liver.

Cytology

Aspirates from metastatic colon carcinoma are usually very cellular and show cells organized in three-dimensional clusters, large sheets, or small groups, or dispersed singly. A palisade arrangement of the nuclei of cancer cells at the borders of a large sheet composed of columnar cancer cells is a characteristic feature of colon carcinoma (Fig. 36-24A,B). Necrosis is very frequent in cytologic preparations from metastatic colon carcinoma. In many of these cases, the cytologic features of the metastasis allow recognition of the primary site, even in the absence of clinical data.

Breast Carcinoma

Breast carcinomas have a high propensity to metastasize to the bone, sometimes many years after treatment of the primary disease. They involve typical skeletal sites, such as the vertebral bodies, pelvis, proximal femur, and humerus, usually in postmenopausal women (Perugia et al, 1984; James et al, 2003). Involvement of the proximal femur with pathological fracture of the femoral neck is a typical sign of advanced breast carcinoma (Nishimura et al, 1999). Lytic bone lesions are typical for breast carcinoma (DiStefano et al, 1979). In a small percentage of cases, metastatic breast cancer may present as a densely sclerotic lesion.

P.1367

Figure 36-23 Metastatic non-small-cell carcinoma of the lung, and follicular carcinoma of the thyroid: cytologic features. *A,B.* Clusters of the large lung adenocarcinoma cells showing obvious cytologic atypia. *C,D.* Groups of loosely arranged small cells forming small follicular structures characteristic of thyroid cancer. Note intranuclear cytoplasmic inclusions and traces of colloid substance in the background of the smears. *Inset.* Higher magnification of thyroid follicular cancer cells with pale cytoplasm and visible nucleoli.

Cytology

Aspirates from metastatic breast carcinoma show three-dimensional aggregates, small clusters, and single dispersed cancer cells of various sizes. It is rarely possible to differentiate between ductal and lobular carcinoma in bone aspirates (Vukmirovic-Popovic et al, 2002). Ductal carcinomas are characterized by the presence of large cancer cells with abundant cytoplasm containing highly atypical nuclei with a clumped chromatin pattern and prominent nucleoli (Fig. 36-24C,D). These cells form irregular clusters with crowding and overlapping nuclei. Aspirates

from metastatic lobular carcinoma are characterized by the presence of relatively small oval cells with eccentric, fairly monotonous hyperchromatic nuclei. Some of these cells, known as “target

P.1368

cells,” contain a large vacuole with central inclusion of condensed mucus (see Chaps. 26 and 29). Nearly all patients with lobular carcinoma have a history of treated mammary carcinoma. In the rare patients with no such history, the disease should be suspected in women of the appropriate age group.

Figure 36-24 Colonic and breast carcinomas metastatic to bone: cytologic features.

A,B. Large sheets of colonic carcinoma cells with overlapping nuclei and focal peripheral palisading. *Inset.* Higher magnification of tumor cells. Note that the individual nuclei of the tumor cells vary in size and contain coarse chromatin with prominent irregular nucleoli. *C,D.* Metastatic ductal carcinoma of the breast shows cells arranged in loose clusters. *Inset.* Details of nuclear morphology with coarse chromatin and prominent irregular nucleoli.

Prostate Carcinoma

Carcinoma of the prostate is a prototypic human cancer that has a unique propensity for osteoblastic bone metastasis (Rana et al, 1993). Solitary or multiple skeletal lesions are frequently part of the clinical picture (Cumming et al, 1990). Features that are associated with a high risk for bone metastasis include high histologic grade (Gleason's combined score ≥ 7), aneuploidy, extraprostatic extension, and involvement of the pelvic lymph nodes (Cheville et al, 2002). Prostatic carcinoma produces densely sclerotic **osteoblastic metastases**, which frequently involve vertebral bodies and the pelvis (Kurt et al, 1990). Metastatic foci can be obliterated by a pronounced osteoblastic reaction. In such cases, aspiration cytology may not be informative and even a core biopsy may contain predominantly sclerotic bone matrix with no microscopically recognizable tumor cells.

Cytology

Aspirates from metastatic prostatic adenocarcinoma are cellular, and the cells may be dispersed singly or create sheets and gland-like structures (Fig. 36-25A,B). Cancer cells have **no distinguishing features** and are usually large with cytoplasmic borders and nuclei with clearly visible large nucleoli. Cytologic preparations from well or moderately differentiated prostatic cancer may contain recognizable microglandular structures that resemble small rosette-like formations, with nuclei at the periphery, and a center formed by amorphous cytoplasmic material (**microglandular complexes**; see Chap. 33). Immunohistochemical stains for prostate-specific antigen (PSA) and prostate-specific acid phosphatase (PSAP) may be used to confirm the prostatic origin of the lesion if there is no history of the disease or there is the possibility of another primary tumor.

P.1369

Figure 36-25 Prostatic and renal carcinomas metastatic to bone: cytologic features.

A,B. Large cohesive sheets of prostatic carcinoma cells. Note that the nuclei of the tumor cells are uniform in size and display only minimal atypia. *Inset.* Higher magnification of tumor cells showing details of nuclear morphology, prominent nucleoli, and evenly distributed chromatin. *C,D.* Metastatic clear-cell carcinoma of the kidney is characterized by loosely arranged clusters of tumor cells with ill-defined clear and finely granular cytoplasm. *Inset.* Tumor cells with clear cytoplasm. Note the mild atypia of the tumor cells, characterized by the presence of round to oval nuclei with clearly visible nucleoli.

P.1370

Renal Carcinoma

Bone metastasis with no evident primary tumor is a **common clinical presentation of renal carcinoma**. About 30% of patients have multiorgan involvement at presentation (Swanson et al, 1981; Althausen et al, 1997). Half of the patients treated for organ-confined disease eventually develop skeletal metastasis (Aggarwal et al, 1972; Viadana and Au, 1975). Renal cell

carcinomas are known to metastasize to unusual sites, such as the skin, tongue, eye, heart muscle, thyroid, and breast (Carter et al, 1977). The acral skeleton may also be involved (Anderson et al, 1968; Fusetti et al, 2003). The typical histologic features of renal cell carcinoma, along with the characteristic clear-cell cytoplasm of the tumor cells, usually make it easy to recognize the origin of the tumor (Taxy, 1981). Renal cell carcinomas typically coexpress keratin, vimentin, and CD10. Progression to a high-grade spindle or pleomorphic sarcomatoid carcinoma is encountered in about 10% of renal cell carcinomas. In such cases, metastases of these tumors may be indistinguishable from primary fibrosarcoma or malignant fibrous histiocytoma of bone (Koss et al, 1992; Katai et al, 1997). When evaluating these tumors, it is essential to use clinical data, as well as immunohistochemical staining, to establish the correct diagnosis.

Cytology

Aspirates from metastatic **conventional** renal cell carcinoma tend to be bloody, **with cancer cells lying singly or arranged in small groups**, and occasionally larger three-dimensional structures. Cancer cells have abundant clear cytoplasm with multiple delicate vacuoles and ill-defined borders (Fig. 36-25C,D). Nuclei have delicate chromatin and conspicuous nucleoli. Cytologic preparations from **metastatic sarcomatoid variant** of renal cell carcinoma show malignant spindle and pleomorphic cells arranged in large sheets or small clusters, or singly, that may be very misleading. The nuclei show pronounced atypia characterized by irregular chromatin clumping and prominent nucleoli. In general, the cytologic features of metastatic sarcomatoid carcinoma are indistinguishable from those of a primary spindle cell sarcoma or malignant fibrous histiocytoma of bone. Immunohistochemical stains for keratin and vimentin, combined with clinical history of primary renal carcinoma, are helpful in establishing the correct diagnosis.

Thyroid Carcinoma

The behavior of thyroid carcinomas varies widely among different histologic variants. Papillary carcinoma typically metastasizes to regional neck lymph nodes. Anaplastic carcinoma is characterized by an aggressive clinical course with wide metastatic involvement of many other organs. Of all of the thyroid cancers, follicular carcinoma has the highest frequency of bone metastasis, which may be the first or late manifestation of the tumor (Boehm et al, 1976).

Radiographically, metastatic thyroid carcinoma forms a destructive lytic lesion of bone (Pittas et al, 2000). Histologically, metastatic deposits show characteristic follicular features with colloid production, and the thyroid origin of metastatic tumor is easily recognizable in most cases (Shah et al, 1981; Tickoo et al, 2000).

Cytology

Aspirates from metastatic thyroid follicular carcinoma show a uniform population of small cells lying singly in three-dimensional clusters, sometimes **forming follicles with central colloid**. Colloid can also be seen as an amorphous substance dispersed in a background of the smear. Characteristically, the nuclei show granular chromatin and clearly visible nucleoli. Intranuclear cytoplasmic inclusions and nuclear “creases” are commonly seen in the spherical nuclei. The cytologic features of metastatic thyroid follicular carcinoma are very distinctive and permit the identification of thyroid origin in most cases (Dhimes et al, 1997). Immunohistochemical stains for thyroglobulin can be used as a marker in questionable cases (see Chap. 30).

PEDIATRIC TUMORS METASTATIC TO BONE

Several pediatric tumors, such as rhabdomyosarcoma, neuroblastoma, and clear-cell sarcoma of kidney, have a unique propensity for metastasizing to bone, and involvement of the skeleton frequently is an integral part of their clinical presentation. On the other hand, Wilms' tumor rarely metastasizes to the skeleton.

Rhabdomyosarcoma

Rhabdomyosarcoma most frequently affects the head and neck area, genitourinary system, and the soft tissue of the extremities in children 3 to 5 years of age. The metastatic foci in the skeleton are usually lytic, with diffuse involvement of multiple bones. Permeative destruction of bone, as observed radiographically, reflects very aggressive behavior of these tumors.

All variants of pediatric rhabdomyosarcomas, such as the **small, spindle, and alveolar cell types**, frequently metastasize to bone.

Metastatic deposits of rhabdomyosarcoma usually recapitulate the morphologic features of the primary tumor.

In most cases, the rhabdomyoblastic features are microscopically recognizable; however, in some cases immunohistochemical markers and molecular genetic studies are

P.1371

needed to differentiate these lesions from other small round or spindle cell lesions. A maturation effect (formation of cross striations) is frequently seen in treated rhabdomyosarcoma. Treatment may significantly change the morphology of the poorly differentiated tumor into large round, oval, or pleomorphic cells with obvious features of rhabdomyoblastic differentiation.

Cytology

The smears from rhabdomyosarcoma are usually very cellular and show a population of malignant small round cells with scanty cytoplasm and round or oval nuclei. The presence of larger cells with abundant eosinophilic cytoplasm containing fibrils or showing cross-striations indicates rhabdomyoblastic differentiation. However, it is difficult to find rhabdomyoblasts that display unequivocal cross striation, and in most cases it is necessary to use immunohistochemical stains to classify the lesion.

Neuroblastoma

Neuroblastoma is a common malignancy of childhood that usually originates in the adrenal medulla (see Chap. 40). Neuroblastoma has a predilection for metastasizing to the skull, orbit, jaws, and metaphyses of long bones. Most patients have widespread disease at presentation. The metaphyseal metastases may clinically and radiologically simulate osteomyelitis.

Microscopically, neuroblastoma is composed of primitive neuroblastic cells that frequently are arranged in small rosettes and produce a delicate intercellular fibrillar matrix. Positive immunohistochemical staining for neurofilaments may be used to identify the neural nature of the cells.

Cytology

Aspirates from metastatic neuroblastoma are usually very cellular and consist of small round cells that occasionally are arranged in clusters and lie singly. A rosette formation composed of spherically arranged nuclei with a fibrillar center may also be present, but this is a rather rare

finding in cytologic preparations. The presentation may be very similar to that of Ewing's tumor (see Fig. 36-20).

Clear-Cell Sarcoma of the Kidney

Clear-cell sarcoma of the kidney is a very rare malignant neoplasm of childhood, with a high propensity for skeletal metastasis (see Chap. 40). **Multiple lytic osseous metastases with an occult primary lesion** are a hallmark of this rare neoplasm. Microscopically, it presents variable patterns with undifferentiated round cells admixed with clear cells. Tumor cells are typically positive for vimentin and negative for keratins.

Cytology

Aspirates from metastatic clear-cell sarcoma of the kidney are usually cellular and show a large population of **pleomorphic sarcomatous cells**. Deep nuclear indentations and nuclear grooves, as well as a granular cytoplasm, are characteristic features (Anderson et al, 1968). In some cases, aspirates may show a biphasic pattern with pleomorphic cancer cells admixed with spindle-shaped cells (Lucas et al, 1994; Katai et al, 1997).

INFLAMMATORY AND REACTIVE CONDITIONS

Inflammation of the bone is a common pathologic condition and most frequently is associated with infection. The infectious process accompanied by inflammation may be blood-borne or may result from direct implantation of microorganisms related to trauma. **Acute hematogenous osteomyelitis** most frequently occurs in children, and *Staphylococcus aureus* is the most frequent pathogen. The major long tubular bones of the appendicular skeleton, such as the femur, tibia, and humerus, are the most frequently affected sites. Hematogenous osteomyelitis may also be seen in immunocompromised adults debilitated by chronic diseases or drug abuse. In these patients, gram-negative and atypical mycobacteria play a dominant role.

Osteomyelitis resulting from trauma, and direct inoculation of bacteria are much more common than blood-borne osteomyelitis. These inflammations usually are polymicrobial, with the presence of staphylococci, streptococci, and gram-negative bacteria.

Chronic osteomyelitis develops in 20% of patients who originally present with acute disease as a result of inadequate antibiotic treatment. **Squamous cell carcinoma** associated with chronic fistula is a late complication of chronic bone inflammation and it typically occurs many years after the original infection. Cytologic preparations of osteomyelitis show chronic or acute nonspecific inflammatory cells.

Osteomyelitis caused by *m. tuberculosis* is seen in approximately 1% of patients who have active disease in other organs (most frequently the lungs). Involvement of the skeleton is typically seen in young patients, and the vertebral column (lumbar spine) is the most frequently involved site. The process starts in the vertebral bodies after hematogenous spread occurs from a primary focus, most frequently in the lungs. The inflammation spreads along ligaments and fascial structures, and may result in the formation of fistulous tracts draining through skin openings in the lower lumbosacral regions (**Pott's disease** or tuberculous spondylitis). Cytologic preparations of mycobacterial infections typically show extensive coagulative necrosis, accompanied by chronic inflammatory cells with epithelioid histiocytes. The presence of mycobacteria can be revealed by culture or special stains for acid-fast bacteria.

Reactive lesions of bone surface, such as florid reactive periostitis, bizarre parosteal osteochondromatous proliferation, acquired osteochondroma (turret exostosis), and subungual

(Dupuytren's) exostosis are pathogenetically **related to myositis ossificans** and are believed to be caused by a clinically evident or subclinical traumatic event. As in myositis ossificans, these lesions evolve from florid proliferative to mature phase. Proliferating spindle and giant cells in the early stage, and periosteal new bone and metaplastic cartilage formation in later stages dominate the lesion. Finally, the lesion matures, producing a **reactive surface osteochondroma**

P.1372

that is incorporated into the underlying cortex and covered by a cartilaginous cap. All of these lesions predominantly affect the small bones of the distal skeleton. Exuberant **fracture callus** may occasionally raise clinical and radiological suspicion of the neoplastic process. These conditions are very rarely diagnosed by cytology (see Chap. 27).

The Mediastinum

Myron R. Melamed

ANATOMY AND CLINICAL CONSIDERATIONS

The mediastinum is the median portion of the thoracic cavity, occupying the space between the lungs and containing all of the thoracic structures except the lungs. It is limited by the pleura of the right and left lungs laterally, by the sternum anteriorly, and by the vertebrae and ribs posteriorly. Despite its limited extent, the mediastinum is the site of a variety of inflammatory and neoplastic processes. Most can be recognized by percutaneous needle biopsy, as was initially demonstrated by Dahlgren and Nordenström (1966) and again in subsequent publications. Cytology of sputum and bronchial secretions, with rare exceptions, has no significant diagnostic role.

Many mediastinal lesions are asymptomatic and discovered as an incidental finding on chest roentgenograms. **Topography is an important factor in making a diagnosis** because the different compartments of the mediastinum are likely to harbor different tumors or other lesions (Fig. 37-1 and Table 37-1). Also of great importance is the **age of the patient**, since many of the mediastinal lesions are age-related. The most important clinical questions to be answered by aspiration cytology are: (1) is the space-occupying lesion neoplastic, inflammatory, or a malformation; (2) if the lesion is neoplastic, is it benign or malignant; and (3) if it is malignant, is it best treated by surgical resection or by irradiation and chemotherapy? **At all times the cytologic findings must be complemented by knowledge of the clinical, roentgenologic, and laboratory data.**

The anterior and middle compartments are the most common sites of mediastinal tumors and benign, space-occupying lesions that include hyperplastic lymph nodes, granulomatous inflammation, and sclerosing mediastinitis.

Although space-occupying benign lesions and primary tumors of the mediastinum are less common than metastatic tumors, they usually present a much greater diagnostic challenge, and therefore are the most likely target of a transcutaneous needle aspiration biopsy. It is essential to accurately identify these lesions before appropriate therapy can be instituted. As mentioned above, close attention to the clinical findings, the location of a lesion in one of the compartments of the mediastinum (see Table 37-1), and the age of the patient are important factors in reaching the correct diagnosis.

Histology of Normal Thymus

The normal thymus varies in size according to age. It is large in infants and children, increases slowly in size until puberty (but relatively more slowly than the growth of the child), and then undergoes progressive atrophy by apoptosis of component cells. In adults it is a vestigial structure, although it retains its basic histologic features.

The thymus is a lymphoid organ supported by a network of anastomizing large **epithelial cells** (Fig. 37-2A-C) joined by desmosomes. Structures known as **Hassall's corpuscles**,

P.1376

which are similar to squamous pearls and are dispersed throughout the thymus, are formed by epithelial cells (Fig. 37-2D). During the maturation in the thymus, **T-lymphocytes** (so named because of their thymic origin) are located within spaces formed by the epithelial cells. The lymphocytes, enveloped by the epithelial cells, form so-called lymphoepithelial complexes. T-lymphocytes, unlike the B-lymphocytes, express both CD-4 and CD-8 antigens. In an interesting observation by Nerurkar and Krishnamurthy (2000), which has not yet been confirmed by others, penetration of lymphocytes into the epithelial cells (or **emperipolesis**) was demonstrated in imprint cytology of the normal thymus.

Figure 37-1 Diagrammatic representation of mediastinal compartments.

PRIMARY TUMORS

Thymic Hyperplasia

As already noted, a large thymus is physiologic and normal in prepubertal children. Benign hyperplasia of the thymus may occur in healthy children or young adults, or as a rebound phenomenon following chemotherapy of malignant tumors, including lymphomas. In such cases,

a clinical differential diagnosis with malignant lymphoma and germ cell tumor may be of critical importance. Needle aspirates of the hyperplastic thymus yield a mixed population of lymphocytes that is unlikely to contain more than a few, if any, benign epithelial or spindle cells. As reported by Bangerter et al (2000), the cytologic smears resemble those of reactive lymph nodes and differ from the monotypic presentation of lymphoma (see Chap. 31), as well as from seminoma and other germ cell tumors (see below). A large thymus in a child may present as a mediastinal mass on chest x-ray, but is not likely to be a thymoma.

**TABLE 37-1 MOST COMMON PRIMARY TUMORS AND SPACE-OCCUPYING LESIONS
ACCORDING TO COMPARTMENTS OF THE MEDIASTINUM**

Superior compartment (i.e., superior to the heart):

Thymoma

Thymic cysts

Lymphoma

Thyroid tumor

Parathyroid tumor

Aneurysms

Hyperplastic and inflammatory lymphadenopathy

Anterior compartment (i.e., anterior to the heart and great vessels):

Thymic hyperplasia

Thymoma

Thymic cysts

Lymphoma

Germ cell tumors

Thyroid tumor

Parathyroid tumor

Hyperplastic and inflammatory lymphadenopathy

Paraganglioma

Soft-tissue tumors (rare)

Posterior compartment (i.e., posterior to the heart and great vessels):

Neurofibroma

Neuroma and ganglioneuroma

Schwannoma

Neuroblastoma and ganglioneuroblastoma

Paraganglioma

Enteric cysts

Middle compartment (i.e., at the level of the heart and great vessels):

Bronchogenic cysts

Enteric cysts

Pericardial cysts

Lymphoma

Aneurysm

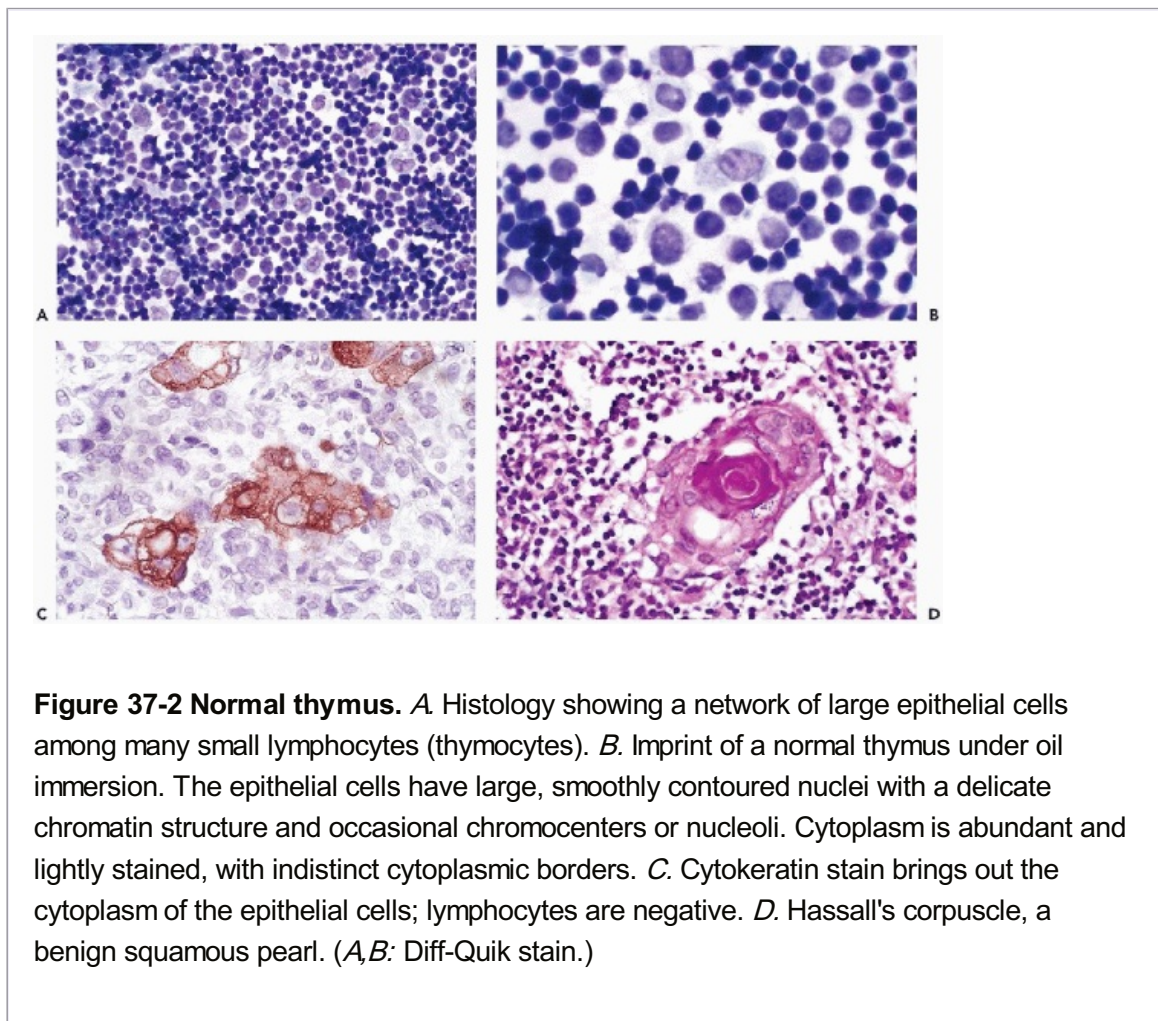

Hyperplastic and inflammatory lymphadenopathy

All compartments: metastatic tumors

Thymomas

Thymomas are tumors of adults. They may be associated with a variety of clinical syndromes that include **myasthenia gravis**, which was found in 46% of patients with thymoma at the Mayo Clinic (Lewis et al, 1987), and in 35% of such patients in Lyon, France (Chalabreysse et al, 2002). Other, less frequent associations include **hypogammaglobulinemia, pancytopenia, red cell hypoplasia, and certain very**

rare immune disorders. Like myasthenia gravis, these disorders may be the first manifestation of thymoma.

Histology

The **dual population of cells** observed in the normal thymus is reflected in thymomas, which are composed of **epithelial cells and lymphocytes** in varying proportions. Most thymomas are encapsulated and benign (Fig. 37-3). The **epithelial component of these tumors may vary from polygonal (Fig. 37-4A-D) to spindly cells (Fig. 37-5A-D)**. Rarely, rosettes and other variants have been described. An elaborate classification of thymomas is not relevant to the context of this book, and the interested reader is referred to other sources for additional information (Shimosato and Mukai, 1997; Rosai, 1999).

Some thymomas that appear histologically benign may invade adjacent lung and even metastasize to other sites. There has been considerable controversy over whether the histologic structure of the epithelial component is predictive of the behavior of the tumor. Thymomas with a predominantly spindly epithelial component are generally believed to be benign, whereas those with polygonal epithelial cells are said to be more aggressive; however, so far there is no conclusive evidence of this behavior pattern. In a review of 90 thymic tumors, Chalabreysse et al (2002) concluded that favorable prognostic factors are noninvasiveness, completeness of resection, younger age, and myasthenia gravis. Thymomas with clear-cut cytologic atypia and numerous mitoses, which are classified as thymic carcinomas by World Health Organization (WHO) criteria, are more aggressive

and invasive. In our experience, the best evidence of malignant potential is invasion through the capsule and into the lung or other tissues. The cytology of frankly malignant thymomas (carcinomas) is considered separately below.

Figure 37-3 Gross appearance of a thymoma. The tumor is sharply circumscribed and soft, pale brown or tan on the cut surface. It is adherent to the adjacent lung (*left*) but noninvasive.

Figure 37-4 Thymoma. *A.* Histologic section showing sheets of epithelial cells with large round or ovoid vesicular nuclei and pale staining cytoplasm with indistinct nuclear borders. Compare with the many small lymphocytes present. *B, C.* At higher magnification, a tumor imprint showing several single thymic epithelial cells with abundant cytoplasm and large round or ovoid nuclei with delicate nuclear chromatin and prominent chromocenters or small nucleoli. *D.* FNA of another thymoma showing epithelial cells in coherent clusters, in

strands of cells and single cells.

Cytology of Thymomas, Excluding Thymic Carcinoma

The aspirates of thymic tumors are typically cellular and, as expected, they demonstrate a **dual population of epithelial and lymphoid cells in variable proportions** (Tao et al, 1984; Sherman and Black-Schaffer, 1990; Koss et al, 1992). The epithelial cells may be present singly (see Fig. 37-4B,C), in clusters (see Fig. 37-4D), or even as tissue fragments (Fig. 37-5C,D). A highly variable number of lymphocytes is intermingled with the epithelial cells. Fragments of fibrovascular tissue may be present. The **epithelial cells** are **polygonal, oval** (see Fig. 37-4), or **spindly** (Fig. 37-5), with moderate to abundant pale cytoplasm and bland, vesicular nuclei that are noticeably larger than the adjacent lymphocytes (see Fig. 37-4B-D). Chhieng et al (2000) estimated the size difference at three- to fourfold. Some degree of **squamous differentiation** of the epithelial cells may be apparent in an aspirate. We have seldom seen well-formed Hassall's corpuscles in thymic tumors, and their presence in an aspirate is in favor of a benign hyperplastic thymus. Chhieng et al (2000) found no Hassall's corpuscles in a recent review of aspirates from 31 patients with thymoma. They reported that thymomas with epithelial cells with round or oval nuclei appeared to be more aggressive than tumors with epithelial cells with spindle nuclei. Chalabreysse (2002) found no such difference, and we also have no evidence that the cell or nuclear shape of the epithelial cells has any prognostic significance (Koss et al, 1992). We agree with Chhieng et al (2000) that cytologic features in the aspirate do not correlate well with any of the histologic patterns.

Although the **population of lymphoid cells** in most thymomas consists of small, resting lymphocytes, it should be noted that intermixed reactive lymphoblasts may be present (Pak et al, 1982; Ali and Erozan, 1998; Shin and Katz, 1998). If the latter are numerous and prominent, one must consider the possibility of a non-Hodgkin's **malignant lymphoma**, which may mimic thymoma, particularly in a child or adolescent (Friedman et al, 1996). For further discussion of thymic lymphomas, see below. **In the absence of lymphocytes, the epithelial cells of thymoma may be mistaken for a primary or metastatic carcinoma.**

Finally, while the presence of a spindle cell population,

P.1379

intermixed with lymphocytes, should suggest the possibility of thymoma, Slagel et al (1997) reviewed 22 cases of mediastinal tumors in which the needle aspirate contained a predominant spindle cell component, and found only two thymomas and two thymic cysts. The remaining cases included nerve sheath tumors, granulomatous inflammation, Hodgkin's disease, and a heterogeneous group of other tumors.

Figure 37-5 Spindle cell thymoma. *A.* The thymic epithelial cells form interlacing bands of elongated cells with thin, spindle-shaped nuclei. *B.* High magnification to demonstrate the spindle cell configuration and pattern of thymic tumor cells. *C.* Diff-Quik stain of the cytologic specimen. *D.* FNA of another case. Note that the tumor cells, which are oval or spindly and uniform, are in clusters or tissue fragments. A spindle cell tumor in the needle aspirate of an anterior mediastinal mass should be considered thymoma until proved otherwise.

Malignant Thymoma (Thymic Carcinoma)

Although the behavior of most thymomas cannot be predicted from their histologic or cytologic presentation, there is a small group of malignant tumors originating in the thymus that deserve to be classified as **thymic carcinomas**. They are characterized by clearly malignant epithelial cells that sometimes mimic squamous carcinoma (Fig. 37-6A-C). The cells are of **irregular configuration with abundant opaque eosinophilic cytoplasm and large nuclei with coarsely clumped chromatin, visible or even prominent nucleoli, and sometimes mitoses**. Necrosis is common. Rarely, these tumors are pure **squamous carcinomas** (Kaw and Esparza, 1993). A few **mucoepidermoid carcinomas of thymus** have been described (Moran and Suster, 1995). Because of their rarity, the behavior of these malignant tumors is not well documented. The tumor illustrated in Figure 37-6 had persisted for a year without major change. In general, poorly differentiated tumors are aggressive and capable of invasion and metastases.

Thymic Carcinoid

Mediastinal carcinoids are uncommon and usually amenable to successful surgical resection. They may have endocrine activity (Wick et al, 1980; Moran and Suster, 2000). The histology of these tumors and the fine-needle aspirates of thymic carcinoid do not differ from those of carcinoids of pulmonary or intestinal origin (see Chaps. 20 and 24). Wang et al (1995) and Nichols et al (1997) described cellular specimens composed of **loosely clustered and single small cells with scant, finely granular cytoplasm and smoothly configured, uniform, round or oval nuclei with granular chromatin and visible small nucleoli**. Unlike small-cell

carcinoma, there is no necrosis and no significant nuclear molding of tumor cells. We have encountered a **spindle cell carcinoid** of the mediastinum. **Carcinoids with oncocyctic features**, which we have seen in the lung (see Chap. 20), were observed in the thymus by Moran and Suster (2000).

P.1380

Positive chromogranin staining of tumor cells can be used to confirm the diagnosis when in doubt.

Figure 37-6 Thymic carcinoma. *A.* Histologic section showing an epidermoid pattern of carcinoma arising in thymus. *B,C.* Needle aspirate showing abundant malignant cells similar to those of a squamous carcinoma.

Malignant Lymphomas

Although the cytologic presentation of malignant lymphomas in the mediastinum is identical to that described for lymph nodes and other organs (see Chaps. 20 and 31), there are some clinical and biologic features that deserve comment. The mediastinum may be the site of **Hodgkin's disease** or of **non-Hodgkin's lymphomas**, which are commonly found in children and young adults.

Hodgkin's Lymphoma

Most cases of mediastinal Hodgkin's lymphoma are of the nodular sclerosing type, and most can be treated effectively by irradiation and/or chemotherapy with excellent results.

Needle aspirates of mediastinal Hodgkin's lymphoma often are sparsely cellular, particularly in the most common nodular sclerosing subtype. However, an adequately cellular specimen yields a characteristic, if not diagnostic, pattern of a few large mononuclear or binuclear Reed-Sternberg tumor cells with prominent nucleoli within a background of lymphocytes, and variable numbers of eosinophils (Fig. 37-7A,B).

Non-Hodgkin's Lymphomas

Two types of non-Hodgkin's lymphomas are principally observed in the mediastinum:

lymphoblastic lymphoma, usually of the T-cell type, which is observed mainly in young adults (mainly males), and **sclerosing, large B-cell lymphoma**, which is seen mainly in young females (Trump and Mann, 1982; Quintanilla-Martinez et al, 1992; Aisenberg, 1999; Suster, 1999). A Burkitt-like lymphoma presenting in the mediastinum was observed by Wolford and Krause (1990) in a patient who had undergone bone marrow transplantation.

The mediastinal lymphoblastic lymphoma usually develops in the thymus, may involve the supradiaphragmatic lymph nodes, and may clinically mimic to perfection a primary thymoma rich in lymphocytes. Cytologically, the lymphocytes show the classic features of a malignant lymphoma: convoluted lymphocytes with indented nuclei.

The large B-cell lymphoma can also present as a thymic lesion, sometimes with occlusion, of the superior vena cava (**vena caval syndrome**). Because of large bands of fibrous tissue, which are common in this lymphoma, it can be mistaken for an epithelial tumor. The lymphocytes have classic malignant features (described in Chaps. 26 and 31).

The experience with transcutaneous aspiration biopsy of these tumors is modest. Silverman et al (1993) described a large-cell lymphoma and stressed the problems of differential diagnosis, mainly with thymoma. In a study of 12 patients, Hughes et al (1998) reported an accurate diagnosis in five patients, and a "suspicious" finding in four. In three patients, the material was insufficient for diagnosis. Other features of the mediastinal large B-cell lymphoma are discussed in Chapter 31.

P.1381

The **differential diagnosis of non-Hodgkin's lymphoma** also includes **benign thymic hyperplasia** (described above), hyperplasia of the mediastinal lymph nodes and, rarely, **Castleman's disease**, which sometimes may have unusual features. For a description of the cytology of Castleman's disease, see Chapter 31.

Neuroblastoma and Ganglioneuroma

Rarely, neuroblastoma presents as a posterior mediastinal tumor in infants and children (usually

under 5 years of age), and half occur in infants less than 2 years old. The histology and cytology of this tumor is repeatedly described in this book and need not be repeated here (see Chaps. 40 and 42). A finding of a tumor composed of or containing ganglion cells is suggestive of a **ganglioneuroblastoma** or **ganglioneuroma**. Figure 37-8 illustrates a paraspinal tumor composed almost entirely of atypical ganglion cells, which was diagnosed as a ganglioneuroma.

Figure 37-8 Ganglioneuroma. Histology (A) and cytology under oil immersion (B) showing a paraspinal tumor composed almost entirely of atypical ganglion cells.

Granular Cell Tumor

Diagnosis of the very rare mediastinal granular cell tumor may be made by percutaneous, transbronchial, or mediastinoscopic needle aspirates in lieu of open thoracotomy with frozen section. As in bronchial brush specimens, the tumor cells in a needle aspirate are large and polygonal with granular cytoplasm and indistinct cell borders (Smith et al, 1998), and are usually accompanied by spindly stromal cells. The cytologic presentation of pulmonary granular cell tumors and breast tumors is discussed and illustrated in Chapters 20 and 29, respectively.

Germ Cell Tumors

Germ cell tumors are so named because they are believed to arise from primordial germ cells. They have the potential to mature into any of the ectodermal, entodermal, or mesenchymal tissues. Most germ cell tumors arise in the gonads; however, they can arise in midline structures elsewhere. The **mediastinum is the most common site for extragonadal**

P.1382

germ cell tumors, which constitute about 20% of mediastinal tumors and are almost as common as thymomas. Takeda et al (2003) reported that 129 germ cell tumors accounted for 16% of all mediastinal tumors seen in a major Japanese medical center over a 50-year period. Of these, mature teratomas (in 95 patients) were the most common, 13 patients had seminomas, and 21 patients had nonseminomatous germ cell tumors.

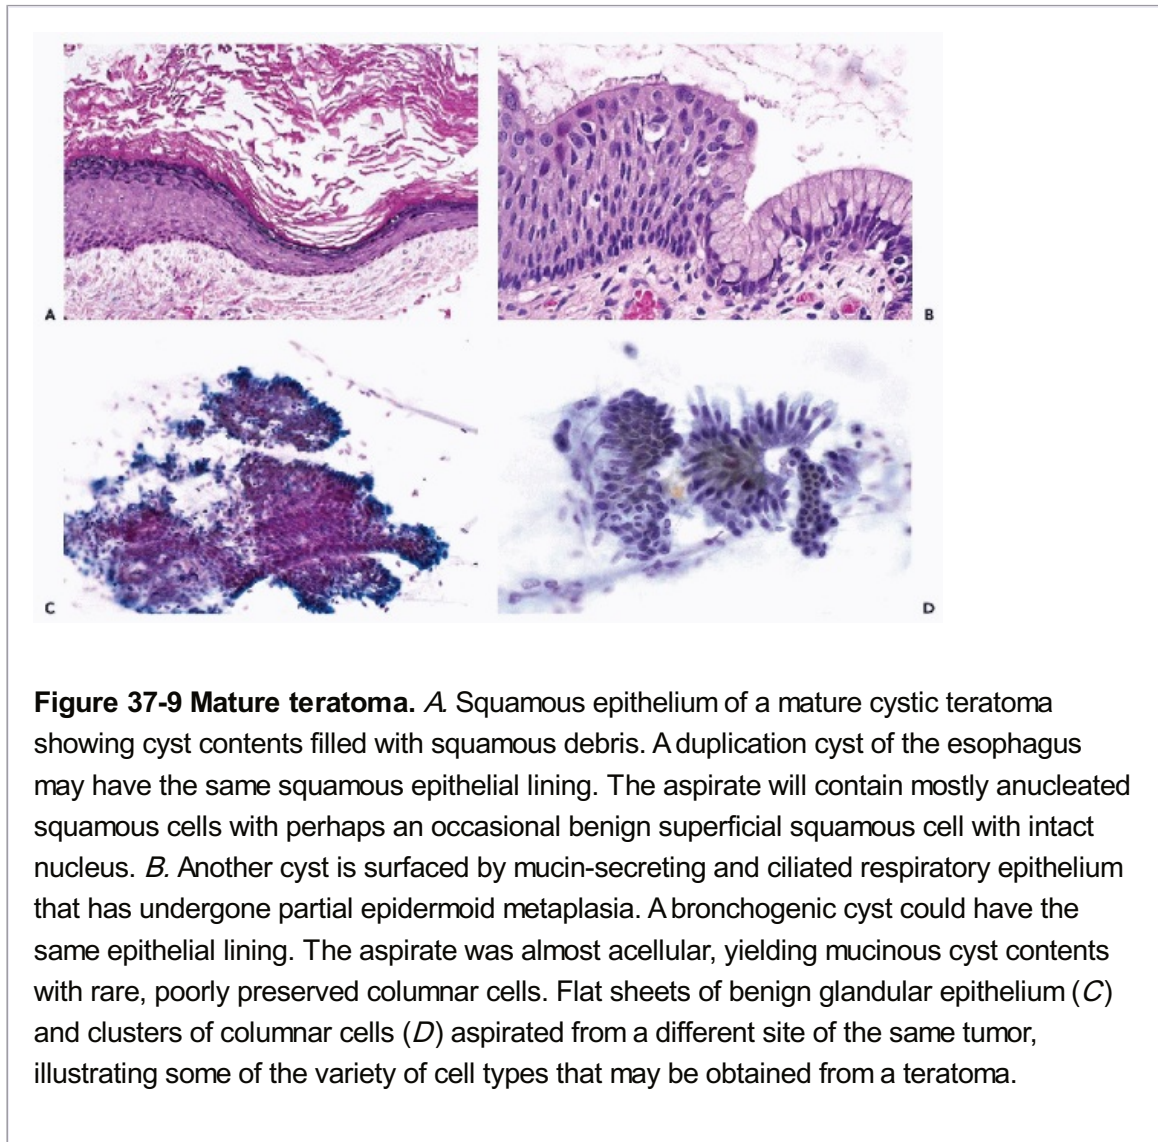

For our purposes, the mediastinal germ cell tumors may be classified as follows:

- **Teratomas (benign or malignant)**
- **Seminomas (germinomas)**
- **Embryonal carcinomas**

- **Yolk sac tumor (endodermal sinus tumor)**

- **Choriocarcinoma**

There is a distinct relationship between the sex of the individual and the occurrence of mediastinal germ cell tumors. **Seminomas (germinomas) occur only in males.** Other germ cell tumors are found predominantly in males but are also found in females. Mature cystic teratomas occur in both sexes in equal proportions (Shimosato and Mukai, 1997). The infrequent immature or partially immature **teratomas of the mediastinum are seen in male children or adolescents.** Needle aspiration cytology of extragonadal germ cell tumors has been described by Tao et al (1984) and Koss et al (1992), and more recently by Collins et al (1995), Motoyama et al (1995), Singh et al (1997), and Chao et al (1997).

Teratomas

Histology

Teratomas are the most common germ cell tumors of the mediastinum. They may be solid or cystic and mature or immature. Histologically, they are composed of tissues from two or three of the embryonic germ cell layers (i.e., the ectoderm, endoderm, and mesoderm). **Mature teratomas are often cystic** and their most common components (in order of frequency) are

skin (Fig. 37-9A), bronchial tissue (Fig. 37-9B), gastrointestinal mucosa, smooth muscle, fat, bone, cartilage, pancreatic tissue, salivary gland, and central nervous tissue (Shimosato and Mukai, 1997). In women, teratomas are virtually always mature and benign, and many

P.1383

are cystic. **Neural tissues** are the **most common immature component** of immature teratomas, and they may constitute a large proportion of the tumor. **Malignant germ cell tumors may arise in an immature teratoma, and carcinomas may arise in mature teratomas.**

Cytology

The cellular content of an aspirate depends on the constituents of the tumor, and is sampling-dependent. Since mature teratomas account for the great majority of mediastinal germ cell tumors, and most are cystic, the aspirate of such tumors will be cyst contents. Thus, an aspirate yielding **squamous keratotic debris or mucoid material should suggest a benign cystic teratoma**. Less commonly, depending on the nature of the tumor and vigor of the aspiration, other tissue components may be observed (Fig. 37-9C,D). Motoyama et al (1995) described sheets of small, somewhat spindly cells in an aspirate corresponding to the neural element of an immature teratoma.

Malignant teratomas yield cancer cells, as described in Chapter 26.

Seminomas (Germinomas)

Histology

Seminomas occur in males; they are often bulky, and in histologic sections are identical to testicular seminomas. They are composed of sheets of **large polygonal cells** with a distinct cell membrane, clear or finely textured cytoplasm, and a centrally placed large round nucleus with delicate chromatin and one or more prominent nucleoli (Fig. 37-10A). Typically there is a **rich population of lymphocytes** separating and surrounding nests or sheets of tumor cells (Fig. 37-10C). Granulomas may occur in these tumors (see Chap. 33).

Cytology

In needle aspirates or imprints, the tumor cells are of **moderate size, dispersed, and quite uniform**. They have **large nuclei with delicate chromatin and a prominent, single, central nucleolus or several smaller nucleoli**, and a rim of scanty, often poorly preserved clear cytoplasm (Fig. 37-10B,D). The **tumor cells typically are accompanied by lymphocytes**. A case of seminoma associated with multilocular thymic cysts was described by Silverman et al (1999).

One of the characteristics of testicular seminoma in air-dried, May-Grunwald-Giemsa (MGG)- or DiffQuikstained smears is a **“tiger-striped” or “tigroid” background** (see Chap. 33) that may also be observed in aspiration smears of mediastinal seminoma (Linsk and Salzman, 1972; Balslev et al, 1990; Collins et al. 1995). The pattern is caused by cytoplasmic debris that, for unknown reasons, are distributed in bands that are not apparent in Papanicolaou- or hematoxylin and eosin-stained smears. Aspirates of **seminoma may be mistaken for large-cell lymphoma, thymoma, or undifferentiated carcinoma**. The cells of seminoma tend to cluster, which distinguishes them from lymphoma, but they are not as coherent as the epithelial cells of thymoma. They are larger than the cells of large-cell lymphoma, and the presence of a second population of small lymphocytes should alert one to the diagnosis of seminoma. A

single, prominent central nucleolus, which is present in many of the cells of seminoma, is highly characteristic of the tumor. In the absence of clinical history, differentiation from metastatic carcinoma may occasionally be a problem, but the cells of carcinoma tend to form organoid groups and clusters, are more variable than seminoma, and may show epidermoid or glandular differentiation. In doubtful cases, the cells of seminoma can be distinguished from those of thymoma by a negative immunocytochemical reaction for cytokeratin, and a positive placental alkaline phosphatase (PLAP) stain. It differs from lymphomas by a negative reaction for CD45 and other lymphocyte antigens.

Embryonal Carcinoma

Embryonal carcinoma is a relatively rare and highly malignant mediastinal tumor that is identical or similar to testicular tumors of this type (see Chap. 33). The histologic pattern typically is variable, and within a single tumor there may be solid, papillary, glandular, or tubular components. In general, the **tumor cells are relatively large, polygonal, with round or oval nuclei, distinct nucleoli, and palestaining cytoplasm with indistinct cell borders**. In aspirates, the cells have scanty cytoplasm and tend to form **groups and clusters, sometimes of a papillary configuration** (see Chaps. 26 and 33). Without knowledge of the patient's age and clinical history, it may not be possible to exclude metastatic carcinoma. The tumor cells are positive for cytokeratin, but like seminoma they may express placental alkaline phosphatase; some, but not all, tumors express alpha fetoprotein.

Yolk Sac (Endodermal Sinus) Tumors

Yolk sac tumors of the mediastinum are also rare and highly malignant, and are similar or identical to ovarian tumors of this type (see Chap. 16). They have a characteristic reticular histologic pattern and so-called “**Schiller-Duval**” **bodies (tiny papillary tufts composed of a central blood vessel surrounded by columnar tumor cells)**. There are intra- and extracellular hyalin, eosinophilic droplets present that are periodic acid Schiff (PAS)-positive, and some are alpha fetoprotein-positive.

Aspirates of mediastinal yolk sac tumors are identical to those in ovarian tumors of this type (see Chap. 15). Collins et al (1995) and Motoyama et al (1995) described **cohesive clusters of cells with large nuclei, vacuolated cytoplasm and PAS-positive intracytoplasmic inclusions and extracellular spherical globules**. Chao et al (1997) found many pleomorphic cells with cytoplasmic and nuclear vacuoles, and aggregates of tumor cells in a **microglandular or papillary configuration**, reminiscent of the Schiller-Duval bodies. Similar findings in **sacroccygeal yolk sac tumors** were reported by Dominguez-Franjo et al (1993).

Choriocarcinoma

Choriocarcinoma is usually seen as a component of other germ cell tumors, and sometimes can be recognized in aspirates by the presence of **large, multinucleated syncytiotrophoblastic**

P.1384

cells with eosinophilic cytoplasm (see Chap. 17). Such a case, in which the choriocarcinoma was associated with embryonal carcinoma, was observed by Sangalli et al (1986) in the mediastinum. Round or polygonal mononuclear cytotrophoblasts are expected to be present but are less distinctive and may not be recognized. The diagnosis can be confirmed by **positive beta-human chorionic gonadotropin (hCG) immunostaining**, which may be useful in cases of suspected metastatic tumor (Craig et al, 1983). For further discussion of the histologic and cytologic presentation of these tumors, see Chapters 17 and 23.

Figure 37-10 Thymic seminoma. Histology of thymic seminoma from a 38-year-old-man (A) and a 49-year-old man (C). The uniform tumor cells have distinct cell membranes, pale eosinophilic or clear cytoplasm, and a central round nucleus with delicate chromatin and one or several prominent nucleoli. Lymphocytes associated with the tumor cells are evident in C. B,D. Corresponding cytology slides for tumors A and B, respectively. Note the prominent nucleolus (or nucleoli) within uniform large round nuclei with delicate chromatin. (B,D: Oil immersion.)

Tumors of Nerve Origin: Schwannomas and Neurofibromas

Schwannomas and neurofibromas are the most common tumors of the posterior mediastinum. The distinction between these two tumors can rarely, if ever, be made by needle aspirate. Histologically, **they are composed of bundles of thin, spindly, often wavy cells** (Fig. 37-11A,B). **The nuclei of Schwannomas may form a palisade-like arrangement (the so-called Verocay bodies)** (Fig. 37-11A,C). The diagnosis should be suspected in a percutaneous needle aspirate of a posterior mediastinal tumor if single and loosely bundled elongated spindle cells are present. Wavy bundles of very elongated cells are most suggestive, and on occasion tumor fragments may be observed with palisaded nuclei (Verocay bodies) (Fig. 37-11C). The diagnosis can be made with confidence if the location of the tumor and radiologic presentation are consistent. The very rare **pigmented schwannoma** may lead to suspicion of melanoma. In percutaneous fine-needle aspirates, however, the tumor cells differ from those of malignant melanoma in that they have long branching cytoplasmic projections that contain the melanotic cytoplasmic pigmentation. The tumors arise in spinal nerve roots and sympathetic ganglia (Marchevsky, 1999), and about half of these tumors contain psammoma bodies (Prieto-Rodriguez et al, 1998). They are S-100 and HMB-45 positive (Marco et al, 1998). Neurofibromas (and, rarely, schwannomas) may be malignant. Jaffer and Woodruff (2000) described such a case with pulmonary metastases and pleural effusion (see Chap. 26).

Solitary Fibrous Tumor

A small number of soft-tissue tumors, classified as solitary fibrous tumors, have been described

in the mediastinum,

P.1385

primarily in the anterior and superior compartments and sometimes associated with thymus. They may be benign or malignant. The former are smoothly encapsulated (Fig. 37-12A) and composed of interlacing bands of spindly fibroblasts in histologic patterns resembling fibrous histiocytoma, hemangiopericytoma, or sometimes neurofibroma/schwannoma (Fig. 37-12B). The cytologic pattern of uniform spindly cells (Fig. 37-12C) is similar to that of other spindle cell tumors, and a presumptive diagnosis of solitary fibrous tumor depends on knowledge of the location and the radiologic appearance of the tumor. The **malignant fibrous tumors** (fibrosarcomas) are characterized grossly by invasive margins and histologically by high cellularity and plump spindle cells with frequent mitoses. The tumor cells express vimentin and CD 34 but are negative for CD 31, cytokeratin, and muscle and glial cell markers.

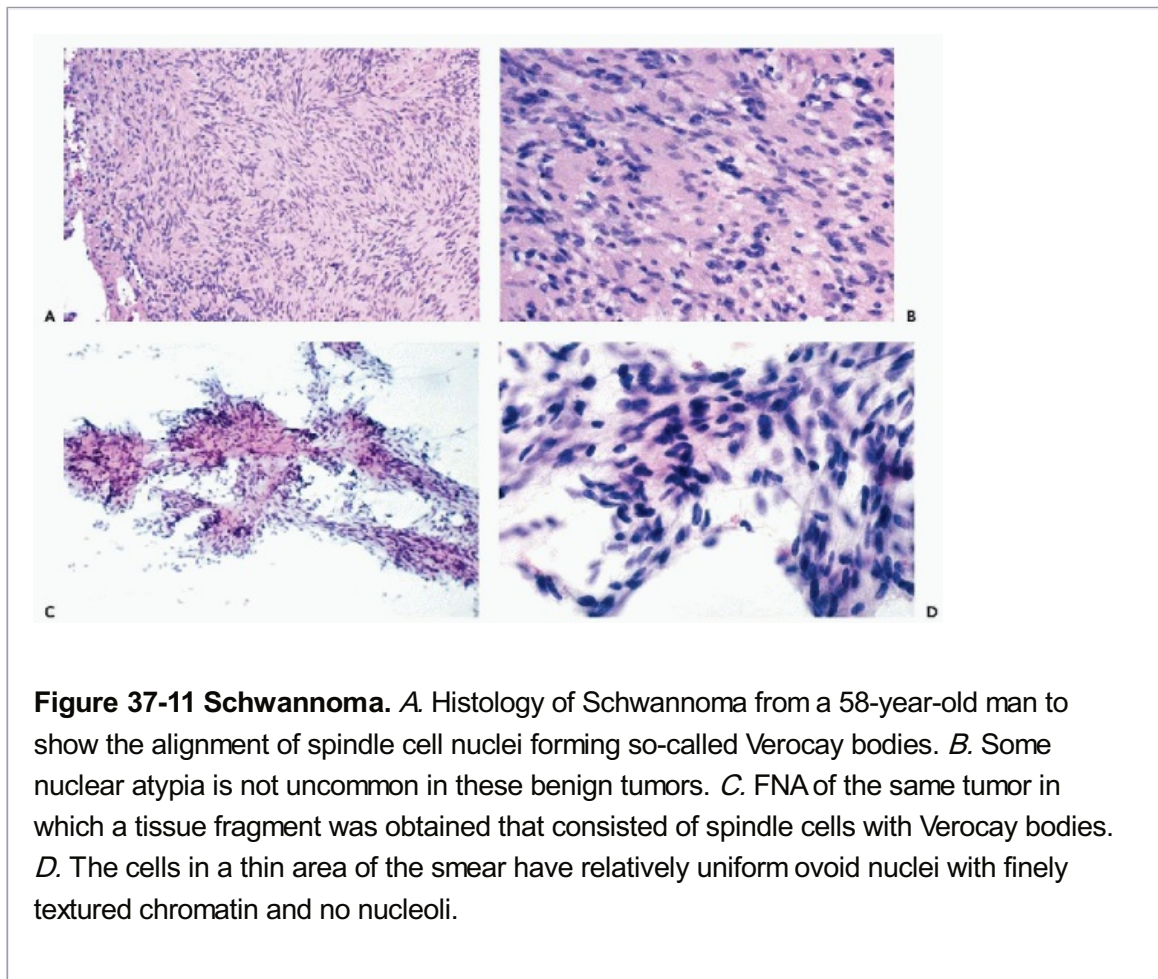

Figure 37-11 Schwannoma. *A.* Histology of Schwannoma from a 58-year-old man to show the alignment of spindle cell nuclei forming so-called Verocay bodies. *B.* Some nuclear atypia is not uncommon in these benign tumors. *C.* FNA of the same tumor in which a tissue fragment was obtained that consisted of spindle cells with Verocay bodies. *D.* The cells in a thin area of the smear have relatively uniform ovoid nuclei with finely textured chromatin and no nucleoli.

Other Soft-Tissue Tumors

The mediastinum may be host to other soft-tissue tumors, such as lipomas, **vascular tumors**, and **sclerosing (fibrosing) mediastinitis**. Attal et al (1995) reported a case of myxoid **liposarcoma**. The reader is referred to Chapter 35 for a description of the cytologic presentation of these tumors.

MEDIASTINAL CYSTS

These cysts are usually an incidental finding on chest x-ray. Symptom-causing cysts are very rare. While it is often quite easy to recognize that one is dealing with a cyst by the presence and appearance of fluid in an aspirate, it may be much more difficult to identify the type of cyst.

As a caveat, many of the usually solid mediastinal tumors may have a cystic component (including, for example, thymoma, mature teratoma (dermoid cyst), seminoma (germinoma), and some lymphomas), and this will be correctly identified only if the aspirate contains a representative sampling of the solid tumor.

Benign congenital thymic cysts may be unilocular or multilocular, and may contain clear or straw-colored fluid, or sometimes old blood. The cysts are thin-walled and lined by epithelium that may vary from flattened to cuboidal to columnar, with or without cilia, or by stratified squamous epithelium. The epithelium may be replaced wholly or partly by granulation tissue. The nature of the aspirate depends on the nature of the cyst contents and the type of lining epithelium involved; however, many cystic tumors of diverse origin contain foamy histiocytes (Fig. 37-13A,B).

Bronchogenic cysts are perhaps the most common benign congenital cysts of the mediastinum. They are **lined**

P.1386

by pseudostratified, ciliated, columnar respiratory epithelium that may undergo squamous metaplasia (see Fig. 37-9B), or they may be denuded. In the absence of respiratory epithelium, these cysts can be recognized histologically by the presence of smooth muscle, tracheobronchial glands, and sometimes cartilage in the wall. **Cytologic confirmation of a radiologic diagnosis depends on finding recognizable respiratory epithelium in the usually sparsely cellular fluid aspirate (remembering that thymic cysts may also be lined by ciliated respiratory epithelium).** In the absence of diagnostic respiratory epithelial cells, one may be able to confirm that a visualized mass is cystic by the nature of the fluid aspirated, but only surmise that the cyst is bronchogenic in origin based on clinical and radiologic presentation.

Figure 37-12 Solitary fibrous tumor. *A.* The benign solitary fibrous tumor differs from its malignant counterpart in that it is smoothly encapsulated. *B.* Histology demonstrates interwoven bands of uniform spindle cells with varying amounts of collagen. The benign tumors may be moderately cellular and even mitotically active. *C.* The cytology slide shows a uniform population of ovoid and spindle cell nuclei with delicate chromatin and thin,

poorly defined cytoplasm. Collagen strands are evident.

Figure 37-13 Thymoma. *A.* Epithelial thymoma showing cystic spaces within the epithelial tumor. *B.* A large thymic cyst containing foam cells.

Esophageal cysts (duplication cysts) are lined by mature squamous epithelium, sometimes with patches of columnar epithelium. The aspirate typically contains many anucleated squamous epithelial cells and squamous debris, usually with few mature nucleated squamous cells. The diagnosis requires correlation with radiologic features that include location within, or closely related to, the wall of the esophagus.

P.1387

Gastroenteric cysts are located in the posterior mediastinum and are lined by gastric or intestinal mucosa. The mucosa does not easily shed recognizable glandular cells, but such cells may be dislodged by the needle. It should be noted that the mucosa is subject to peptic ulceration and complications thereof, which may affect the nature of the cellular aspirate.

Pericardial cysts are lined by a single layer of flat or cuboidal mesothelial cells, and contain clear, straw-colored fluid. They may or may not be attached to the pericardium (if not, they may be classified simply as mesothelial cysts). If it is not complicated by inflammation or hemorrhage, the straw-colored, sparsely cellular fluid will contain only a few mesothelial cells and mature lymphocytes.

Lymphatic cysts contain straw-colored or milky fluid that can be sparsely cellular or rich in lymphocytes. The endothelial lining cells are unlikely to be present or recognized.

Parasitic cysts are described elsewhere. **Hydatid cysts**, which may occur in the mediastinum and in the lungs of patients living in endemic areas, can be diagnosed definitively by the finding of scolices or chitinous cyst lining in an aspirate (see Chap. 19).

MISCELLANEOUS LESIONS

Chronic inflammatory processes in the mediastinum may form masses that may be suspected clinically or radiologically to be neoplastic. Most are caused by infectious agents and are similar to processes involving the lung. A case of **candida mediastinitis**, diagnosed by endoscopic ultrasound-guided fine-needle aspiration (FNA) cytology, was reported by Prasad et al (2000). Bakhos et al (1998) recently reported a **mediastinal inflammatory pseudotumor** that was diagnosed by FNA. The cytologic characteristics of aspirates from inflammatory

lesions involving the lung are described in Chapter 19.

Hiller et al (1995) reported a case of **mediastinal amyloid tumor** diagnosed by FNA.

Endometriosis involving the lung and pleura was diagnosed by Granberg and Willems (1977).

METASTATIC TUMORS

Metastatic carcinomas, principally from the lung, breast, and esophagus, are the most common tumors of the mediastinum. They usually involve mediastinal lymph nodes but may extend to soft tissues. The metastatic deposits are seldom aspirated, because the diagnosis is usually evident clinically. If they are aspirated, however, the cytology is identical to that described for the lung and lymph nodes in Chapters 20 and 31, as well as other chapters, and need not be repeated here. **Transbronchial needle aspirates of mediastinal lymph nodes**, as described by Baker et al (1990), have been used for the staging of bronchogenic carcinoma. Baker et al (1990) pointed out that the presence of lymphocytes is an essential criterion of specimen adequacy. As discussed above, a cytologic distinction between primary and metastatic malignant tumors is not always easy, and it often requires a thorough knowledge of clinical and radiologic findings.

ACCURACY OF MEDIASTINAL ASPIRATES

Potential sources of error with mediastinal aspirates are noted above, and were previously discussed by Geisinger (1995). Because of the generally limited experience with needle aspirates of the mediastinum at any one institution, there are no large series that can provide statistically reliable data on diagnostic accuracy. In a review of 189 mediastinal aspirates from four academic institutions, Singh et al (1997) found that only 15% of the cytologic samples were unsatisfactory. There were very few errors among the remaining satisfactory aspirates: one small-cell carcinoma was mistaken for malignant lymphoma, and one germ cell tumor was mistaken for metastatic carcinoma. In general, given pertinent clinical and radiologic information and an adequate sample, the experienced examiner should be able to achieve a high level of diagnostic accuracy with aspiration cytology specimens from mediastinal space-occupying lesions.

The Liver and Spleen

Muhammad B. Zaman

THE LIVER

Diseases of the liver can be broadly divided into diffuse parenchymal disorders, such as hepatitis and cirrhosis, and space-occupying lesions, such as cysts, abscesses, and benign or malignant tumors. The latter group is the target of fine-needle aspiration biopsy (FNA), which is performed under imaging guidance [**ultrasonography (US) or computed tomography (CT)**], usually by an interventional radiologist. Lundquist (1971) attributed the actual introduction of the aspiration of the liver to Lucatello in 1895.

At most institutions, including ours, the liver is the most commonly aspirated abdominal organ, accounting for 55% of abdominal aspirates and 36% of all aspirates performed by radiologists.

SAMPLING TECHNIQUES

CT and US can be used to guide the **selection of the entry site for a liver aspiration biopsy**, and provide information on the depth to which the needle will be inserted and the optimum angle of approach to the target. The entry site is selected based on the **shortest distance between the skin and the target lesion**. This entry site may be modified in order to **avoid the costophrenic angles** (and hence the danger of **pneumothorax**) and **major vessels**, such as the aorta, vena cava, and portal veins.

The patient is placed in a comfortable supine position, usually leaning to the left. Following the selection of the entry site, the skin is cleansed and anesthetized. A 2- to 3-mm skin incision made with a no. 11 scalpel blade facilitates the passage of the biopsy needle. The needle, with the stylet in place, is inserted through the skin incision at the previously determined angle and depth. The insertion of the needle is performed during suspended respiration and usually in the same respiratory phase employed in the previous localizing study. Special care and experience are required to prevent the direction of the thin, flexible needle from being deflected, particularly in patients with well-developed musculature. This problem can be avoided by initially inserting a rigid 18-gauge needle with a stylet to the depth of subcutaneous fat and muscle. Subsequently the stylet is removed and replaced by the thin needle, which is then advanced to the target. As the needle reaches the target, the operator is often able to sense a change in the consistency of the tissue. Five to 10 rapid (4- to 5-mm) excursions of

P.1390

the needle are performed to loosen the cells. Suction is applied by attaching a 10- or 20-ml disposable syringe to the thin needle. This is followed by a few short excursions through the lesion, while the suction is continued. **The suction must be released before the needle is withdrawn. Except for cysts with a large fluid content, the aspirated material should remain within the needle.** The operator can repeat this procedure three to four times through

the same skin incision, using a different needle and slightly modifying the angle of approach.

Recently there have been further innovations in the technique. An 18-gauge spring-driven biopsy gun (Automatic Disposable Guillotine Soft-Tissue Needle; Bauer Medical Inc, Clearwater, FL), similar to the device extensively used for a Tru-Cut prostate needle biopsy, is employed. A 15-cm-long, 1.5-mm-wide outer needle with a stylus is first introduced under CT guidance to reach the lesion. The longer (20 cm), precocked, 18-gauge biopsy gun is then introduced to the appropriate depth and multiple slender tissue cores are obtained for cytologic and histologic studies. An immediate assessment of a core can be performed with smears, prepared as crush or touch preparations, stained with Diff-Quik. Two to four smears from each biopsy can be prepared. It was previously documented by Sherlock et al (1967), Grossman et al (1972), and Carney (1975) that the **cytologic evaluation of residual debris** accompanying large core needle biopsies increases the diagnostic yield in malignant diseases in comparison with histologic evaluation. In our experience, in 5% to 10% of cases of metastatic cancer, only benign liver tissue is seen in routine histologic sections of hepatic biopsies (cut at six to eight levels), whereas smears disclose malignant cells. Thus, cytologic and histologic studies of liver biopsies are complementary and the use of both methods can increase the diagnostic sensitivity (Bell, 1986; Dusenbery et al, 1995). The reported sensitivity of tumor diagnoses ranges from 67% to 100%, and the specificity ranges from 80% to 100% (Schwerk et al, 1981; Walker et al, 1982; Samartonga et al, 1992; Hertz et al, 2000).

Complications

FNA of the liver is considered a very safe procedure. Anecdotal cases of fatality secondary to hemorrhage have been reported (Riska et al, 1975), and bleeding disorders are considered a contraindication. The other reported complication is bile peritonitis (Schultz, 1976). At Montefiore Medical Center, we observed a similar case occurring in a patient with pancreatic carcinoma and distended gall bladder (Courvoisier gall bladder), and a case of fatal hemorrhage following aspiration of a hepatic angiosarcoma (Rosenblatt et al, 1982; Koss et al, 1992). DeMay (1996) recorded several cases of seeding of primary and metastatic malignant tumors of the liver after these diagnostic procedures were performed. In some of these procedures, large-caliber needles were used.

TABLE 38-1 PRINCIPAL SPACE-OCCUPYING LESIONS OF THE LIVER

Benign
Hepatic cysts
Congenital
Hydatid
Abscesses

Hamartomas
Malignant
Primary tumors
Hepatocellular carcinoma (HCC)
Hepatoblastoma
Cholangiocarcinoma
Rare primary tumors
Metastatic tumors

Indications

FNA of the liver is widely used in the **evaluation of space-occupying lesions**. The principal targets are listed in Table 38-1. In metastatic cancer, the superiority of the guided needle approach over the transcutaneous tissue core biopsy performed with large-bore needles (Vim-Silverman- or Menghini-type needles) has been documented, particularly for lesions in the left lobe of the liver (Rosenblatt et al, 1982).

As discussed below, FNA of the liver **does not replace tissue biopsy for the evaluation of diffuse hepatic disorders such as cirrhosis, hepatitis, suspected granulomas, or metabolic diseases**, in which the histologic context is important. However, an incidental cytologic examination may sometimes contribute to the diagnosis in such cases.

NORMAL LIVER

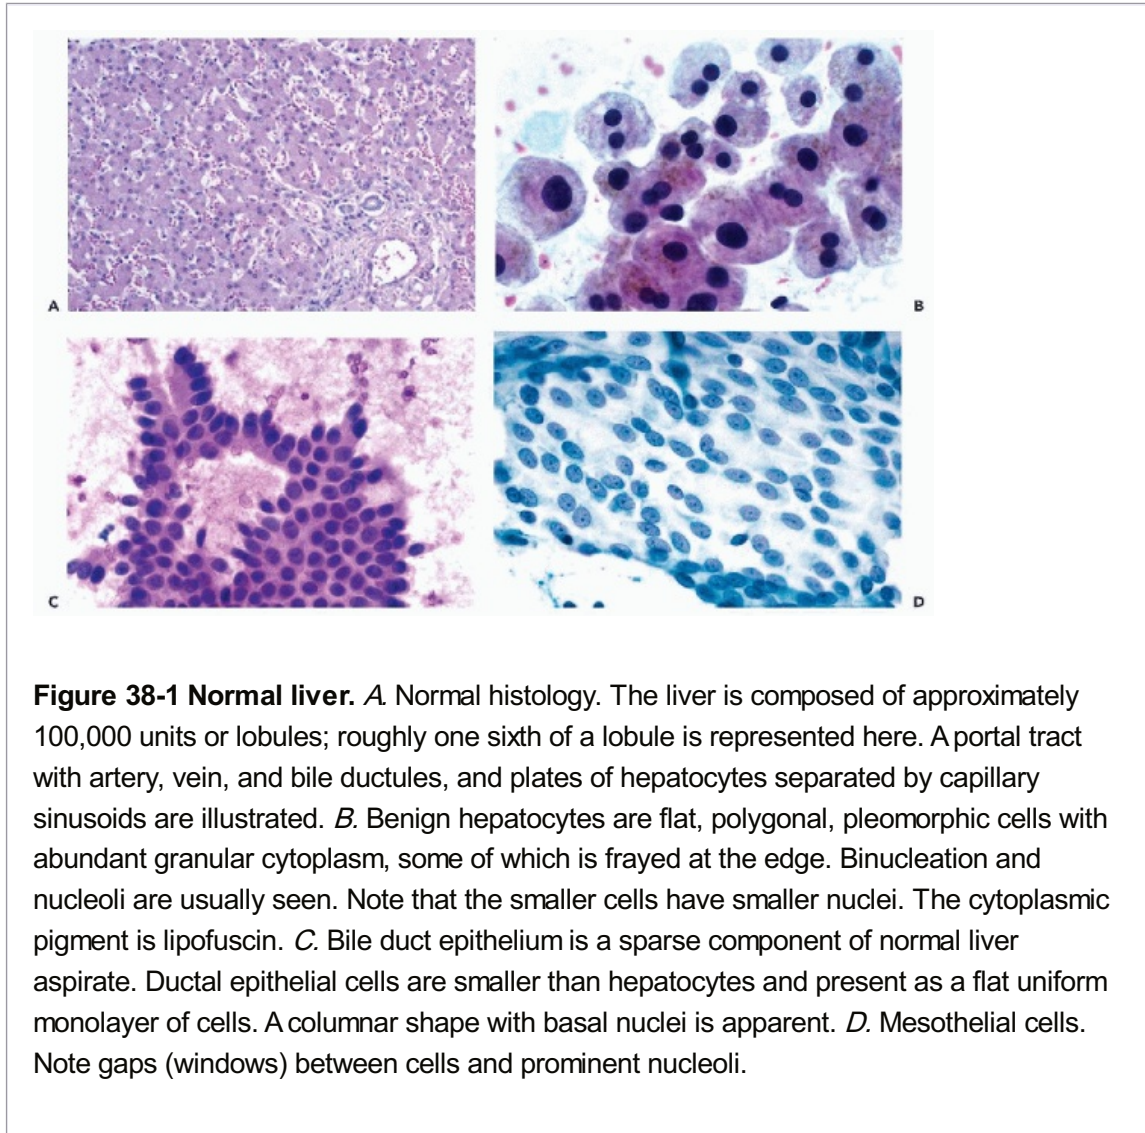

Histology

The liver is enclosed in a thin layer of connective tissue surfaced by a single layer of mesothelial cells (**Glisson's capsule**), and is separated from the right diaphragm by a narrow space. Normal liver is composed of numerous **lobules, each of which is formed by large hepatocytes** arranged in plates that are separated from each other by capillary vessels (Fig.

38-1A). The endothelial cells of these capillaries, **the Kupffer cells**, have a **phagocytic function**. Rare, small perisinusoidal cells, **hepatic stellate cells** (Ito cell or fat-storing cell), become prominent in hypervitaminosis

P.1391

A. The hepatic lobules are separated from each other by **portal spaces**, or areas of connective tissue, that contain small bile ducts and branches of the portal vein and hepatic arteries.

A characteristic feature of the metabolically very active **hepatocytes** is the **granularity of their cytoplasm**, which is caused by the presence of numerous organelles (mainly mitochondria). Most, but not all, **nuclei** of normal **adult hepatocytes** are **tetraploid**, which accounts for their relatively large sizes.

One of the principal functions of hepatocytes is the **formation of bile**, which is collected in tiny intercellular **bile canaliculi**. These canaliculi merge to form intralobular bile ducts that may be visualized by special stains, such as **CK19** (Hurliman et al, 1991; Maeda et al, 1995, 1996; Alexander et al, 1997). The intralobular ducts merge to form larger bile ducts that are visible in portal spaces and eventually deliver the bile into the common bile duct, which opens into the duodenum. The **smaller bile ducts** are lined by cuboidal cells, and the **larger ducts** are lined by columnar cells with clear cytoplasm and small vesicular nuclei.

Cytology

Normal liver is never deliberately aspirated, but normal hepatocytes and bile duct cells are a common component of smears, particularly if the target of the aspiration is a relatively small space-occupying lesion. Mesothelial cells, which are derived from the mesothelial lining of Glisson's capsule (see below), are a common component of such smears.

Normal and Reactive Hepatocytes

Hepatocytes occur singly or form loosely cohesive groups of large, **flat polygonal cells** with abundant, **dense granular cytoplasm** that stains pink with hematoxylin and eosin, and purple with hematologic stains (such as Diff-Quik) or orange-brown with Papanicolaou stain (Fig. 38-1B). Quite often, the cytoplasm is frayed at the edge. Perinuclear accumulation of **lipofuscin** pigment may be present in older patients (see below). The **single or double nuclei** of hepatocytes are spherical, have a regular contour, are centrally placed within the cell, and may **vary in size in keeping**

P.1392

with their DNA content. The chromatin is moderately granular and evenly distributed, and small **nucleoli** are visible. **Intranuclear cytoplasmic inclusions** (INCLs) are not uncommon.

Normal hepatocytes show some variability in size, and thus some degree of pleomorphism. However, a **low nucleocytoplasmic ratio** is maintained (i.e., smaller cells have smaller nuclei). In rapidly fixed material, hepatocytes in clusters may be separated from each other by **narrow clear spaces** that represent **intercellular bile canaliculi**. **Kupffer cells** are rarely identified unless they act as macrophages and contain phagocytized material in their cytoplasm.

Bile Duct Epithelium

Bile duct cells usually form **flat, cohesive clusters** with distinguishable cell borders (i.e., a **honeycomb arrangement of cells**). Cells derived from small bile ducts are **cuboidal**, whereas **larger columnar cells**, similar to the endocervical epithelium, are derived from larger ducts. In both types of cells, the nuclei are transparent, uniform, ovoid, and basally placed (Fig. 38-1C). In normal liver aspirates, bile duct cell clusters are **relatively uncommon**. The only situations in which they may represent the **dominant population** in an FNA smear are those involving a **bile duct adenoma (peribiliary gland hamartoma)** and **bile duct hamartoma** (see Fig. 38-17). Conversely, a **total absence of bile duct epithelium in an adequate FNA of liver with uniform, relatively small hepatocytes** should raise the suspicion of **liver cell adenoma or a well-differentiated hepatocellular carcinoma (HCC)**.

Mesothelial Cells

During the aspiration, the needle must penetrate the serosal surface of the abdominal cavity and Glisson's capsule before it reaches the target. Therefore, if the needle stylet is withdrawn before the needle enters the liver, **sheets of mesothelial cells** with characteristic intercellular clear spaces or "windows" may be observed. A **characteristic feature of these cells is the presence of visible, sometimes multiple nucleoli within the oval or spherical, granular nuclei**. In some liver smears, particularly if the aim of the aspiration is a small subcapsular lesion (e.g., a hemangioma), only mesothelial cells may be present. If such smears are inexpertly prepared, the sheets of mesothelial cells may be disorganized. Because of their nuclear features, the mesothelial cells may be **mistaken for cancer cells** (Fig. 38-1D).

Hemopoietic cells are seen in **extramedullary hematopoiesis**, which may occur normally in infants but in adults is a consequence of impaired bone marrow function. **Large, multilobate**

megakaryocytes are usually the most conspicuous cells in such smears (see Fig. 40-22).

PIGMENTS IN LIVER CELLS

Lipofuscin

This very common pigment, which is located predominantly within the perinuclear area of centrilobular hepatocytes, forms **fine nonrefractile brown to golden-brown granules** in Papanicolaou-stained smears (Fig. 38-2A). The pigment is composed of tertiary lysosomes that accumulate as end-products of intracellular digestion, and the amount of pigment increases with age. Lipofuscin can be stained with **acid-fast stain (Fite stain)**, and has no particular clinical significance; however, it may be confused with other pigments that may accumulate in pathologic states.

Bile

Intracellular bile is a nonrefractile pigment that stains green to greenish-brown in Papanicolaou stain, and dark blue in Diff-Quik stain. Bile is produced only by hepatocytes, and in well-fixed smears the pigment is observed in **tiny intercellular bile canaliculi**. Otherwise, the pigment is diffuse in the cytoplasm. Accumulation of bile in **benign hepatocytes** is associated with **hepatitis or obstructive jaundice**. In the latter condition, bile may also be observed as yellow-green **extracellular crystals** (Fig. 38-2B). The presence of bile in **the cytoplasm of malignant cells is diagnostic of primary or metastatic HCC**.

Hemosiderin

Hemosiderin is a **coarse, golden-brown refractile pigment** that can be seen in the cytoplasm of hepatocytes, Kupffer cells, and, rarely, in bile duct epithelium. Its identity can be confirmed by stains for iron, such as Prussian blue. Its presence in hepatocytes indicates iron overload that **may lead to cirrhosis**. This may occur in an iron metabolism disorder (e.g., **hemochromatosis**) or after numerous transfusions (e.g., **hemosiderosis**) (Fig. 38-2C,D).

Melanin

This pigment is usually associated with metastatic melanoma to the liver. This is a powdery cytoplasmic pigment that stains brown in Papanicolaou stain (see Fig. 38-23A) and blue in Diff-Quik stain. The pigment may also be phagocytized by Kupffer cells. For further discussion of metastatic malignant melanoma, see below.

Copper

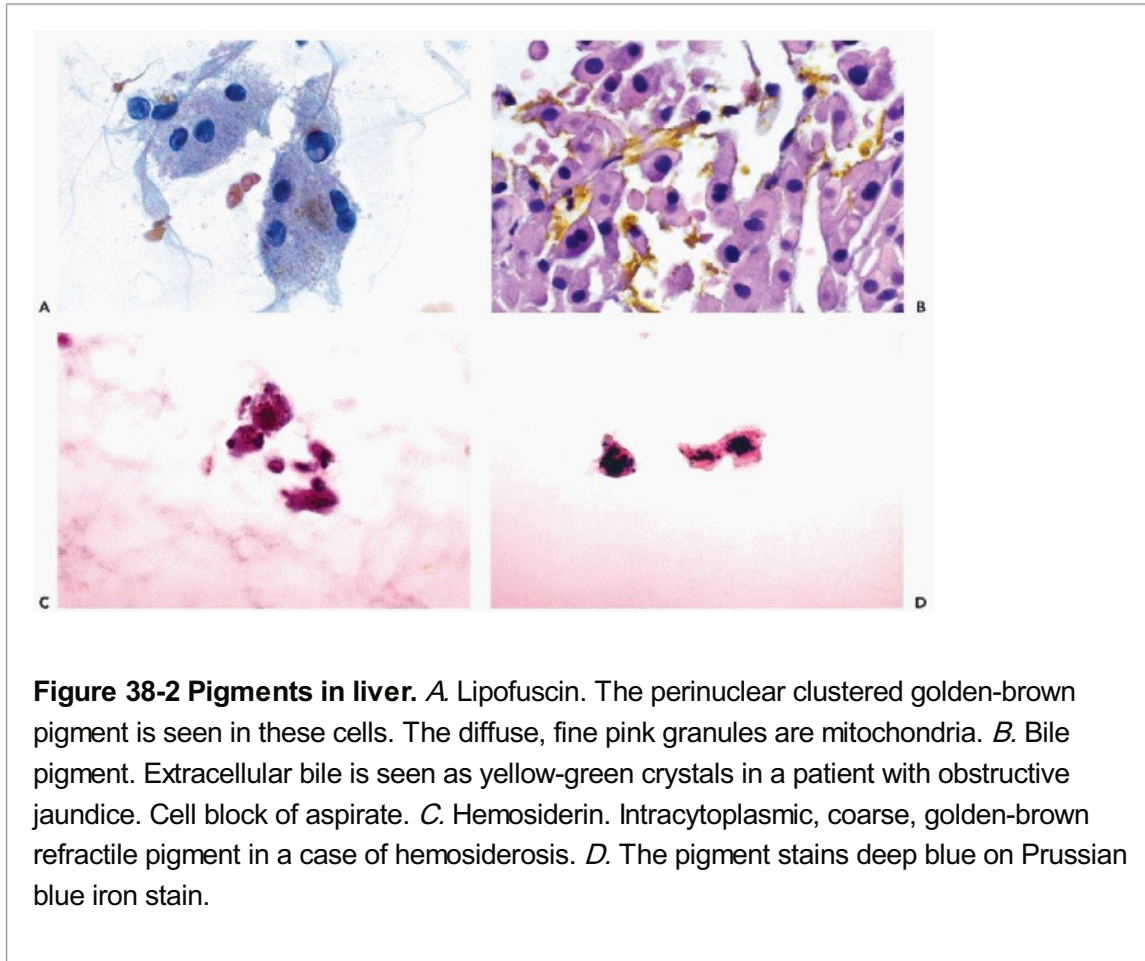

This coarse, green-brown pigment is seen in a perinuclear cytoplasmic location in the hepatocytes of patients with **copper metabolism disorders, such as Wilson's disease, Indian childhood cirrhosis** (possibly caused by excessive dietary intake of copper resulting from the use of copper or brass cooking and storage vessels), **primary biliary cirrhosis**, and other chronic cholestatic disease (Sipponen et al, 1980). Special stains are necessary to identify copper.

DIFFUSE DISEASES OF THE LIVER

Limitations of FNA

As mentioned in the introductory comments of this chapter, aspiration biopsy smears are generally inadequate for the

diagnosis of diffuse or medical diseases of the liver, which require the use of **tissue biopsies, preferably representing six to 12 portal tracts**. However, occasionally aspiration smears combined with other laboratory data may contribute to the differential diagnosis of these disorders, particularly in ruling out suspected HCC. The two principal disorders in this category are **cirrhosis** and **chronic hepatitis**.

Cirrhosis

Histology

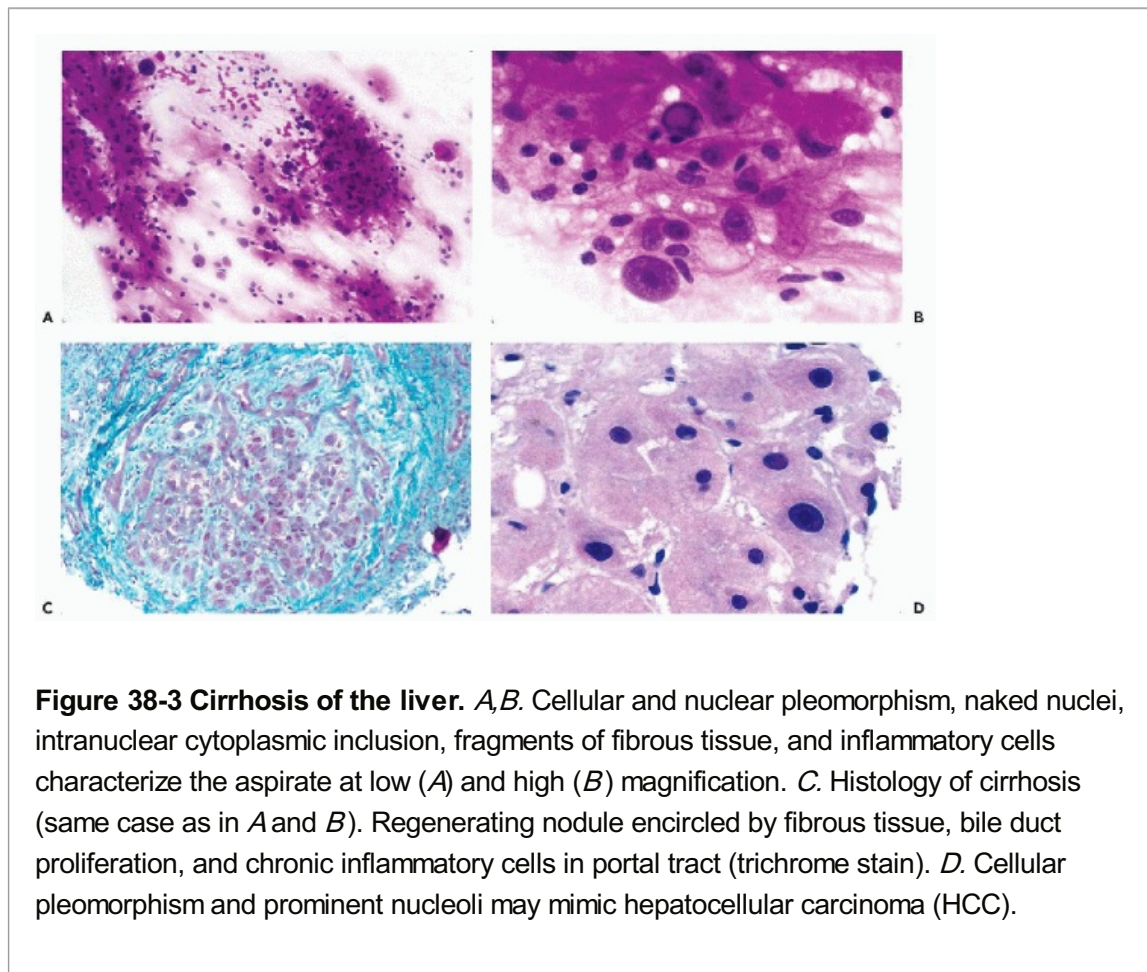

Cirrhosis, which is an essentially irreversible process, may be the **end stage of alcoholic liver disease** or of **chronic hepatitis caused by hepatitis virus B or C**. Excessive **growth of portal connective tissue**, with a resulting subdivision of the liver into visible and palpable **coarse nodules of various sizes**, is the essence of the cirrhotic process (Fig. 38-3C). Within the nodules, **necrosis and regeneration of hepatocytes** may take place, and this process is thought to be involved in the pathogenesis of HCCs that may complicate cirrhosis. Within the enlarged portal spaces, there is usually a marked **proliferation of bile ducts** and an inflammatory infiltrate composed mainly of lymphocytes. Because the pathologic subdivision of the liver parenchyma disturbs the normal circulation of blood with increased portal venous pressure, the various manifestations of cirrhosis include esophageal and periumbilical (**caput medusae**) vein enlargement or varices, enlargement of the spleen, and accumulation of ascitic fluid (Koss et al, 1992). Hemorrhages from the esophageal varicose veins may be fatal to the patient. In general, cirrhotic livers are not investigated by FNA. However, on CT scans cirrhotic nodules may mimic HCC, and this may lead to an aspiration.

Cytology

The cellular and nuclear **pleomorphism of hepatocytes** with many multinucleated cells (some with intranuclear cytoplasmic inclusions) is the hallmark of cirrhosis (Fig. 38-3A,B). The nuclei may also vary in size, and some may show prominent nucleoli. However, the nucleocytoplasmic ratio is usually not altered (Fig. 38-3D). Fragments of fibrous tissue that incorporate pleomorphic hepatocytes or encircling hepatic nodules are occasionally present in smears (Fig. 38-3A) (Lundquist, 1970). **Bile duct epithelium** is usually well represented, a **feature that is not seen in FNA of large HCC**. The latter finding is very helpful because when the cellular pleomorphism is very marked, and particularly in the presence of occasional **large, hyperchromatic nuclei with prominent nucleoli** stripped of cytoplasm, the differential

P.1394

diagnosis of cirrhosis from HCC may pose problems (Berman, 1988; Koss et al, 1992).

Biliary Cirrhosis

Biliary cirrhosis is an uncommon **autoimmune disorder** that mainly affects women and leads to the destruction of bile ducts. A characteristic feature of this disorder is the presence of **antimitochondrial antibodies** (for recent reviews see Tanaka et al, 2001; Bogdanos et al, 2003; Zuber and Recktenwald, 2003). This disorder is rarely, if ever, dignosed by needle aspiration biopsy. It is mentioned here because occasionally an HCC will develop in such patients (Morimoto et al, 1999).

Chronic Hepatitis

The diagnosis of chronic hepatitis, particularly that caused by hepatitis virus C, requires the use of **core biopsies**, which are assessed by an elaborate grading and staging system (Ishak et al, 1995). An incidental FNA performed because of suspicion of HCC will reveal **hepatocytes that vary in appearance from essentially normal to pleomorphic**, as observed in cirrhosis (see above). The presence of scattered lymphocytes may suggest the correct diagnosis. Mummified, shrunken, eosinophilic, necrotic hepatocytes (**Councilman or acidophilic bodies**) may be seen.

Metabolic Disorders

Inborn hereditary errors of metabolism that diffusely involve the liver and are seen in pediatric-age groups are not a primary indication for an aspiration biopsy. The reader is referred to any standard textbook of pathology to review the natural history and microscopic findings in such disorders, which include alpha-1-antitrypsin deficiency, cystic fibrosis, glycogen storage disease type IV, mucopolysaccharidosis, porphyria cutanea tarda, and erythropoietic protoporphyria.

Some metabolic disorders are amenable to primary FNA biopsy diagnosis (e.g., **amyloidosis** (Bose, 1989) and sometimes **Gaucher's disease**) (see Fig. 38-25). Others result in the deposition of pigments in the hepatocytes (e.g., **hemachromatosis and Wilson's disease**), as discussed above.

Cytoplasmic **vacuoles containing fat (fatty liver or steatosis)** are attributed to **faulty metabolism or alcoholic liver disease** (Fig. 38-4A). **Regenerating liver**, following partial resection, may show enlarged nuclei with prominent

P.1395

nucleoli and steatosis. Such changes are sometimes termed "reactive atypia," and should be reported with an explanatory note (Fig. 38-4B).

Figure 38-4 Metabolic disorders. A. Steatosis or fatty liver. Note the accumulation of lipid in the cytoplasm of the hepatocytes. The finding is nonspecific and can be seen in many forms of liver injury. B. Reactive atypia in regenerating liver, after partial resection for HCC. Vacuoles containing fat are seen.

Obstructive Jaundice

Jaundice can be caused by a **variety of benign or malignant conditions that lead to the obstruction of the hepatic or common bile duct**. The role of aspiration smears of liver in the diagnosis of obstructive jaundice is limited. Bile duct proliferation, acute inflammation, bile stasis, and normal hepatocytes have been reported as the characteristic findings (Henriques,

1977). Intra- and extracellular bile accumulations are usually seen in FNA (see Fig. 38-2B). If the obstructive jaundice is caused by a primary or metastatic cancer, cytologic studies may contribute significantly to the diagnosis and treatment of this disorder (see Chap. 24).

Granulomatous Disorders

Granulomas in the liver may be caused by a variety of disorders, such as **sarcoidosis, tuberculosis or other infections, drugs, neoplasms, and hepatobiliary disorders (e.g., primary biliary cirrhosis)** (Neville et al, 1975; Wee et al, 1995). The granulomas are usually small and dispersed, and therefore the specific diagnosis cannot be established in 50% of tissue core biopsies. The histologic prototype of granulomas is a nodular collection of epithelioid histiocytes with or without giant cells, some with central necrosis. Sometimes granulomas can be recognized in FNA smears, but their specific etiology is seldom apparent (see Chaps. 19, 29, and 31). Thus it is usually difficult to diagnose granulomatous liver disorders (Stormby and Åkerman, 1973).

SPACE-OCCUPYING BENIGN CYSTIC LESIONS

Congenital Cysts

Most hepatic cysts are congenital. Such cysts are often associated with polycystic disease affecting the kidneys; they are generally asymptomatic and incidentally discovered during US or on CT scans. The cysts vary greatly in size and may be solitary or multiple, and uni- or multilocular. They are smooth-walled and generally subcapsular in location. Some cysts may become calcified. Such cysts are more common in women, are thought to arise from cystic dilatation of bile ducts, and rarely require treatment. Very large cysts may produce pressure symptoms, such as pain, and very rarely may lead to an obstruction of the bile flow and cause jaundice. The cysts are lined by a **single layer of flat or cuboidal small epithelial cells, which resembles** bile duct epithelium. Malignant tumors occurring within hepatic cysts are extremely rare (Bloustein, 1977).

The aspirated fluid is **clear and straw-colored**. Smears of spun-down sediment show **numerous large macrophages with small nuclei** (Fig. 38-5A), similar to the contents of renal cysts. Small, **flat clusters of benign cuboidal epithelial cells** may be observed (Fig. 38-5B). Normal hepatocytes may also be present in smears.

A rare variant of congenital cysts is the **ciliated hepatic foregut cyst**, which is lined by ciliated epithelium and is similar to a bronchogenic cyst of the mediastinum. The content is viscid and mucinous, and smears may show a large number of macrophages and columnar cells bearing well-preserved cilia (Fig. 38-5C,D) (Zaman et al, 1995). Vick et al (1999) described a case of **squamous carcinoma** that occurred in a foregut cyst.

Hydatid Cysts

Hydatid cysts are caused by the larvae of the **dog tapeworm, *Echinococcus granulosus***. Most cases occur in people from sheep- and cattle-raising areas of the world, including the United States, where dogs are the usual definitive host. Generally, children are infected following the accidental ingestion of eggs, which hatch in the intestine. Embryos penetrate the intestinal wall and enter the bloodstream. It takes many years for the **unilocular hydatid cysts** to develop, which commonly occurs in the right lobe of the liver, and less often in the lungs (see Chap. 19).

Figure 38-5 Cysts in liver. *A,B.* Congenital hepatic cyst. A cytospin smear shows large and small macrophages in a background of cell debris. *B.* Bile duct epithelium from the cyst lining may be present. *C.* Ciliated hepatic foregut cyst. Columnar cells bearing well-preserved cilia in a mucus background. Macrophages are also present. *D.* Hepatic foregut cyst. The resected cyst is lined by ciliated pseudostratified columnar epithelium. *E.* Neoplastic cyst. The FNA appearance of a mucinous cyst in a 77-year-old female. Cytologically benign glandular cells in monolayer in a clean mucinous background are in favor of a primary tumor. *F.* Histology of the resected cyst. The epithelium is hyperplastic and papillary, with dysplastic changes. An ovarian-like stroma is present.

P.1397

The **wall of each cyst** is composed of a thin **germinal layer** supported by a 1-mm-thick laminated membrane and an external thick laminated fibrous capsule that may partly calcify. The germinal layer is studded with **daughter cysts known as brood capsules**. Each capsule contains several heads or scoleces of the larval form of the parasite, with the **characteristic hooklets**. The aspirated cyst fluid usually contains **hydatid sand**, a mixture of degenerated scoleces, hooklets, calcareous corpuscles, and small fragments of the germinal layer (Garret et al, 1977; Pogacnik et al, 1989; Koss et al, 1992) (Fig. 38-6A,B). **If the diagnosis is established clinically, an aspiration is not indicated because spillage of the cyst contents may result in dissemination or anaphylactic shock.**

Hepatic Abscesses

Hepatic abscesses are of bacterial or amebic origin. **Bacterial abscesses** may be

complications of ascending cholangitis, septicemia, appendicitis, subphrenic abscess, or trauma, or they may have no clear predisposing cause. They may be single or multiple and contain **bile-stained pus**, which is easily recognized in aspirated material. Abundant intact or fragmented polymorphonuclear leukocytes (PMN), some lymphocytes, and debris containing macrophages are seen in the smears. Bacteria are often visible. **Necrotic and reactive hepatocytes** may be noted (Fig. 38-6C,D). Aspiration and drainage of the pus may be of therapeutic value.

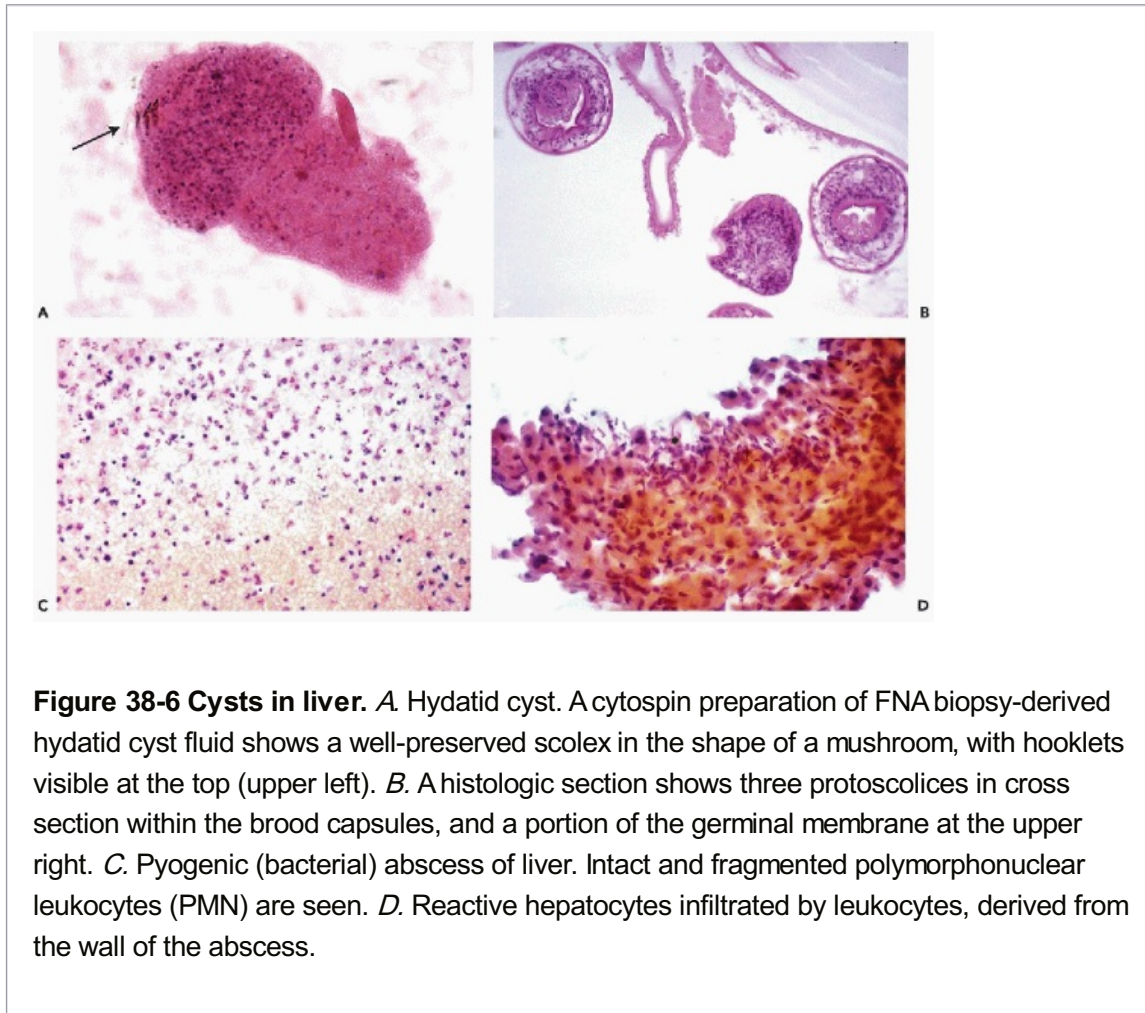

Figure 38-6 Cysts in liver. *A.* Hydatid cyst. A cytospin preparation of FNA biopsy-derived hydatid cyst fluid shows a well-preserved scolex in the shape of a mushroom, with hooklets visible at the top (upper left). *B.* A histologic section shows three protoscolices in cross section within the brood capsules, and a portion of the germinal membrane at the upper right. *C.* Pyogenic (bacterial) abscess of liver. Intact and fragmented polymorphonuclear leukocytes (PMN) are seen. *D.* Reactive hepatocytes infiltrated by leukocytes, derived from the wall of the abscess.

Amebic liver abscesses caused by *Entamoeba histolytica* are uncommon in the Western world. Chronic amebic dysentery is endemic in countries where drinking water is contaminated by fecal material, and liver abscess is a common complication. The smears of amebic abscesses contain necrotic material and macrophages. Occasionally, **amebic trophozoites** containing ingested erythrocytes can be identified, provided that the material was obtained from the wall of the abscess.

Neoplastic Cysts

The **very rare hepatic biliary cystadenomas and cystadenocarcinomas** are nearly all of the mucinous type and are analogous to pancreatic cystic tumors. Relatively large series involving these cysts have been reported in the literature (Ishak et al, 1977; Wheeler et al, 1985; Pinto et al, 1989; DeVaney et al, 1994). The multilocular cystic tumors are almost exclusively seen in women (95%) and measure 2.5 to 28 cm in diameter. They are **lined by cuboidal or columnar**

mucinous epithelium with dense subepithelial fibrous stroma, which rarely may calcify and thus mimic hydatid cyst on imaging. In some borderline cases [seven of 52 in DeVaney et al's (1994) series], the cyst lining contained **foci of "dysplasia"** manifested by multilayering, hyperchromasia, and loss of polarity of the lining epithelium. Rare malignant cystadenocarcinomas have also been described (Ishak et al, 1977). The cyst content is clear and mucinous, and less often is serous, bile-stained, brown, or gelatinous, or consists of hemorrhagic fluid. The presence of carcinoembryonic antigen (CEA) on assay separates the neoplastic from congenital or hydatid cysts (Pinto et al, 1989). Aspirated cyst content in smears may only show the benign lining epithelium in a clean mucinous background (see Fig. 38-5E,F). As expected, complete resection of benign cysts is curative. However, when they are malignant, the 4-year survival rate is only 50% (DeVaney, 1994). Occasionally, **primary HCCs** and the rare **primary carcinoids may be cystic**.

BENIGN TUMORS OF THE LIVER

Hemangiomas

The rather common benign hemangiomas are largely asymptomatic and are usually discovered, incidentally, during abdominal imaging by US or CT as **well-circumscribed, space-occupying masses**. **Cavernous hemangiomas** may reach large sizes and cause pressure symptoms. They sometimes may be difficult to distinguish radiologically from primary or metastatic carcinoma (Nakaizumi, 1990), although magnetic resonance imaging (MRI), angiography, or radioisotope imaging may be diagnostic of the entity. A needle aspiration of hemangiomas is not recommended because of the danger of hemorrhage; however, if it is performed, the smears will show **blood, sometimes scanty fragments of fibrovascular connective tissue**, and benign liver cells (Brant, 1987). Cell block preparations may yield diagnostic fragments of tissue (Fig. 38-7E).

Adenomas

Clinical Data and Histology

These uncommon, usually encapsulated neoplasms occur mainly **in young women who have used contraceptive hormones** for an extended period of time (Christopherson et al, 1977; Fichner, 1977; Tao, 1991). The tumors may reach substantial sizes, causing abdominal discomfort, a palpable liver mass, or a hemorrhage caused by rupture of the lesion, which may lead to a hemoperitoneum.

The tumors are composed of **poorly organized liver parenchyma** and show **hepatocytes of variable sizes. Portal spaces and bile ducts are absent**. HCC may occur in these patients. Tao (1991, 1992) suggested that the foci of certain cytologic abnormalities, which he named **"dysplasia,"** may occur in adenomas, and may constitute a link between an adenoma and an HCC. **If α -fetoprotein (AFP) in the serum of a patient with adenoma is significantly elevated, a diagnosis of a well-differentiated HCC must be considered**. The two entities are sometimes difficult or impossible to distinguish histologically, even in resected specimens (Berman et al, 1988).

Cytology

Experience with the cytologic presentation of these lesions in FNA is very limited. Tao (1991, 1992) described nine such adenomas, seven of which were characterized by the presence of **abundant benign hepatocytes**. The hepatocytes, some of which formed large, three-

dimensional cohesive groups, appeared essentially **normal**, with smooth nuclear membranes (Fig. 38-7A-C). Perhaps of diagnostic significance was the **absence of epithelium of the bile ducts**. In the two adenomas with **foci of dysplasia**, Tao observed cellular and nuclear abnormalities identical to those observed in a well-differentiated HCC (see below).

Focal Nodular Hyperplasia

Clinical Data and Histology

Focal nodular hyperplasia (FNH) is an encapsulated, sometimes pedunculated tumor that is often observed at the periphery of the liver. In contrast to adenomas, which occur nearly exclusively in adult women, FNH may be observed in **both sexes and all age groups**. The asymptomatic lesions may be single or multiple, and are usually smaller than adenomas. They are discovered incidentally during imaging studies of the liver. The lesions have an uncertain prognosis because while some of them may disappear, others will increase in size. In contrast to adenomas, there is no evidence that these lesions are precursors of HCC (for a recent summary see Bioulac-Sage et al, 2002).

The anatomic structure of FNH is fairly characteristic. Grossly and on a CT scan, the **center of the lesion is occupied by an area of fibrosis that is described as a central stellate scar**. It must be noted, however, that a similar radiologic appearance can sometimes be seen in sclerosing HCC, hemangioma, or metastatic cancer (Shirkhoda et al, 1994).

Histologically, the lesion is characterized by a **central area of fibrosis that contains malformed arterial vessels** but no branches of the portal vein (Fig. 38-7D). At the periphery of the fibrotic area, **malformed bile ducts** can be observed. The remainder of the lesion is composed of nodules of benign hepatocytes separated by uneven bands of fibroconnective tissue containing capillaries lined by **Kupffer cells**. A radionuclide scan **demonstrating Kupffer cells** is virtually diagnostic of nodular hyperplasia (Shirkhoda et al, 1994). The presence of **eosinophilic hyaline inclusions** in the cytoplasm of the hepatocytes was reported by Wetzel and Alexander (1979).

Cytology

Experience with aspiration cytology of FNH is limited. In a personally observed patient, sheets of small but otherwise normal **hepatocytes** were accompanied by **bile duct cells**, some typical and some **forming long tubules**, corresponding to the rudimentary bile ducts observed in FNH (Fig. 38-7D) (Koss et al, 1992). Others have reported similar

P.1399

findings (Nguyen, 1986; Ruschenburg and Droese, 1989; De May, 1996). In our judgment, the diagnosis can be established if hepatocytes are accompanied by atypical bile duct epithelium and, sometimes, by fibrous tissue. The presence of bile duct epithelium rules out adenomas and HCC.

Figure 38-7 Aspiration smear of a liver cell adenoma with tissue follow-up. *A.* Interconnecting nests and cords of relatively small uniform hepatocytes characterize this smear from a 34-year-old woman with a long history of oral contraceptive use. *B.* Higher magnification confirms the absence of nuclear atypia or prominent nucleoli. A conclusive diagnosis of hepatocellular adenoma vs. well-differentiated HCC could not be made. *C.* Resected tumor. The absence of the classic trabecular pattern, a relatively low nuclear-to-cytoplasmic (N/C) ratio, absence of vascular invasion, and normal α -fetoprotein (AFP) level favored a diagnosis of hepatocellular adenoma. *D.* Focal nodular hyperplasia (FNH). Nodules of benign hepatocytes separated by bands of fibroconnective tissue with malformed bile ducts and arterial vessels. *E.* Hemangiomas. Cell block preparation of a cavernous hemangioma of liver showing dilated vascular spaces lined by endothelium. The compressed capsule shows bile ductules. The FNA smears showed fresh blood only.

PRIMARY MALIGNANT TUMORS OF THE LIVER

The diagnosis of a malignant tumor of the liver, whether primary or metastatic, carries (with rare exceptions) a grave prognosis. Despite the progress made in early diagnosis, liver surgery (including transplantation), and hepatic artery infusion with chemotherapeutic agents during the last decade, there is no evidence that a significant reduction in mortality has occurred or that the drastic therapeutic procedures are cost-effective (Collier et al, 1998). FNA of the liver is an essential procedure for the diagnosis of these tumors.

Hepatocellular Carcinoma (HCC)

Epidemiology

HCC accounts for approximately 80% of all primary malignant tumors of the liver. It is one of the most common cancers in Asia and Africa, where it is conspicuously associated with hepatitis B virus infection. Immunization against hepatitis B virus has been shown to be of value in reducing

P.1400

the rate of HCC in Taiwan (Chang et al, 1997). **Aflatoxin**, which is produced by the fungus *Aspergillus flavus*, has been implicated in Asia and Africa as a cofactor of hepatocellular and bile duct carcinomas (Jaskiewicz et al, 1991; Wogan, 1992). In India, China, Japan, and Korea, a parasite that dwells in the duodenum—*Clonorchis sinensis*—has been implicated as a cause of HCC and intrahepatic cholangiocarcinoma (ICC) (Belamaric, 1973; Purtilo, 1976; Kim, 1984; Choi et al, 1988; Parkin et al, 1992; Shin et al, 1996; Abdel-Rahim, 2001).

Although HCC is still rare in the United States, the incidence of this cancer is on the rise (El-Serag and Mason, 1999). The annual incidence of primary cancers of liver and intrahepatic bile ducts in 2002 was estimated by the American Cancer Society to be 16,600 patients and 14,100 deaths (Jemal et al, 2002). Ninety percent of American patients with HCC have an **underlying cirrhosis** (Edmondson and Steiner, 1978). **The cirrhosis is either secondary to alcoholism or chronic viral hepatitis associated with either B or C virus.**

The occurrence of HCC in **normal liver**, with no serologic evidence of hepatitis, is unusual and limited to about 2% of patients (Melato et al, 1989; Nzeako et al, 1996). Some of these cases are attributed to the **use of contraceptives** (via adenosis; see above) **or anabolic steroids**, **administration of Thorotrast for diagnostic purposes** (a practice abandoned many years ago), **or metabolic disorders**, such as tyrosinemia and α -1 antitrypsin deficiency.

Figure 38-8 HCC. A. Subcapsular tumor of the right lobe, resected from a 63-year-old man with cirrhosis secondary to chronic hepatitis C. C. The tumor measured 8 cm in diameter, was encapsulated, and further subdivided into nodules by fibrous septa. Areas of hemorrhage and focal necrosis, as well as evidence of bile (yellow-green) production, are noteworthy. B, C. A very well-differentiated HCC in an aspiration smear with relatively small cells resembling benign hepatocytes (compare with Fig. 38-1B). There are many naked nuclei crowded together. Slender endothelial cells are also present and are helpful in diagnosing HCC. D. Core needle biopsy of a very well-differentiated pseudoglandular HCC

corresponding to A-C. Individual cells show very little atypia. (B,C: Diff-Quik stain.)

Clinical Presentation and Prognosis

The vast majority of patients with HCC in the United States are **men over the age of 60 years with liver cirrhosis**. Conversely, approximately 10% of patients with cirrhosis will develop HCC (Berman, 1988). The common clinical presentation of the tumor is a **right upper quadrant mass, abdominal pain, weight loss, and ascites** (the latter being secondary to cirrhosis). Cytologic examination of the ascitic fluid may reveal striking mesothelial cell abnormalities caused by cirrhosis, but seldom cells of HCC, and thus the fluid rarely contributes to the diagnosis (Koss, 1992) (see Chap. 25). Symptoms caused by metastases as the initial presentation of HCC are rare and occur in only 3% to 5% of patients (Okuda, 1997).

Although the most common presentation of HCC in imaging studies is a **single large liver mass** (Fig. 38-8A),

P.1401

the tumor may also form **multiple smaller nodules** or a **dominant mass with satellite nodules**, thus **mimicking the more common metastatic cancer**. Also, a malignant tumor observed in an otherwise normal liver is most likely a metastasis. **Serum alpha-fetoprotein (AFP) is elevated in about 60% of patients with HCC, and is the most useful marker for HCC**. However, the level of AFP must be **above 500 ng/ml** to be of diagnostic value, because while acute or chronic viral hepatitis and cirrhosis also cause elevation of this enzyme, it is rarely above that level (Saul, 1999). In nearly 30% of AFP-seronegative patients (mainly those with small or well-differentiated HCC) the serum level of **des-γ-carboxyl prothrombin (DCP)** has been suggested as a useful marker, with a sensitivity of 60% to 90% and specificity of 85% (Weitz et al, 1993). Thus, the decision **as to whether a tumor is primary or metastatic**, which is of critical therapeutic and prognostic significance, often rests in the hands of the cytopathologist, who assumes a critical role in the management of liver masses.

HCC tends to **invade blood vessels**, and may spread to the portal vein system and the inferior vena cava. A CT survey at the **initial presentation of HCC will show metastatic disease in approximately 60% of cases**, primarily to lymph nodes of the porta hepatitis, but also to distant sites such as the lung, adrenal, or bone. At this stage of the disease (stages IIIB and IV), there is no effective treatment and survival is limited to a few months (Nzeako et al, 1996; Okuda et al, 1997). Even if the disease is localized to the liver, surgical resection or liver transplant are often impractical because of the underlying cirrhosis. Tumor size above 5 cm is, at present, a contraindication for a liver transplant. The 5-year survival after resection of selected cases is reported to be 20% to 30%. With stringent preselection (tumor ≤5 cm, in noncirrhotic or compensated cirrhotic patients), the 5-year survival rate can exceed 50% (Bruix, 1997). Except for the **rare fibrolamellar variant** of HCC, which arises in the normal liver of children and young people, and is more frequently resectable with prolonged survival, the prognosis depends on the tumor stage and the patient's performance status. Prognostically, the histologic pattern or degree of differentiation is not significant.

Histology

HCC is a malignant tumor derived from hepatocytes. The main histologic characteristic of very well-differentiated HCC is its resemblance to the normal liver in both its platelike growth and its cytomorphology (Wee et al, 1991) (Fig. 38-8D). This is the basic appearance of the various histologic subtypes described below.

A **trabecular (sinusoidal, plate-like) pattern** is the most common type of HCC. The tumor cells grow in cords, three to several cell layers thick, separated by sinusoidal **thin-walled capillaries**. Kupffer cells are absent. Large cavernous spaces may be formed (see Figs. 38-10D and 38-11D). In some cases, the tumor grows as a **solid mass** wherein the sinusoids may be rendered inconspicuous by compression, and is classified as **compact (solid) pattern** (see Figs. 38-8D and 39-9D).

A **pseudoglandular (tubular or acinar) pattern** usually results from a central breakdown of otherwise solid tumor trabeculae. The content of these gland-like spaces vary from macrophages and cellular debris to homogenous colloid-like material. A **glandular pattern** can also result from dilatation of canaliculi between tumor cells, and may contain dark-brown inspissated bile (Figs. 38-8D and 38-9D). The tumor cells may assume a columnar shape, thus resembling an adenocarcinoma.

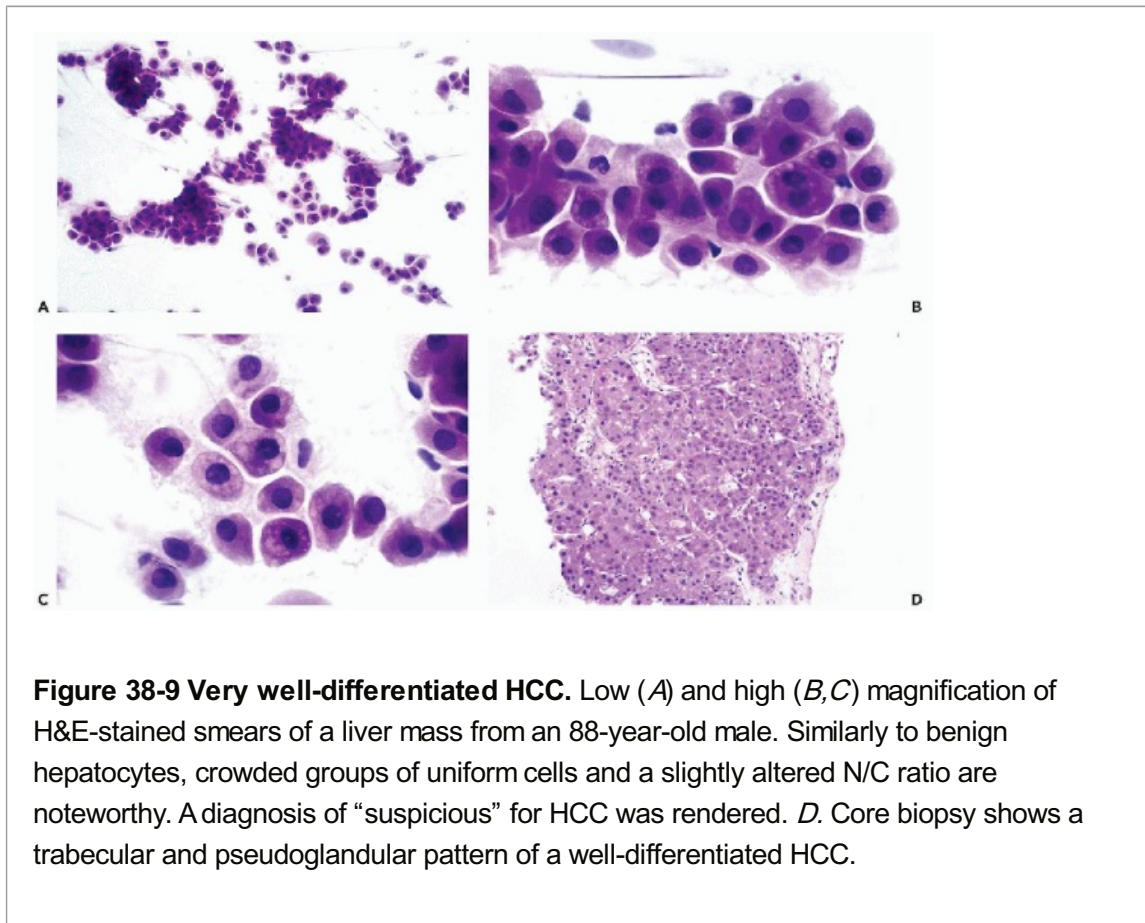

A **fibrolamellar variant**, which constitutes about 5% of primary hepatomas, occurs predominantly in children and young adults with noncirrhotic livers. Although sporadic reports of this tumor type appeared earlier, the term was first coined by Craig et al (1980). The unique nature of this hepatoma was also stressed by Berman et al (1980). The tumor is composed of **large polygonal cells** with abundant granular eosinophilic cytoplasm (**oncocyte-like cells**), sharply defined cell borders, and large vesicular nuclei with prominent nucleoli. The nests and columns of cells are separated by parallel (fibrolamellar) **hyalinized bands of collagen** (see Fig. 38-14C). Cytoplasmic pale bodies (ground-glass cells) are often seen. The latter is immunoreactive for fibrinogen (Berman et al, 1980). Approximately 50% of the tumors show bright pink periodic acid-Schiff (PAS)-positive intracytoplasmic hyaline globules (Fig. 38-14C), which are frequently immunoreactive for α -1-antitrypsin (Saul, 1999). A clear-cell variant was described by Cheuk and Chan (2001). The relationship of these tumors to FNH is being debated (Saul et al, 1987). This group of tumors has a distinctly better prognosis than more conventional types of hepatomas.

A **clear-cell variant** is characterized by tumor cells with prominent, clear cytoplasm caused by loss of glycogen and fat during processing. Nucleoli may be very prominent; thus, the histologic and cytologic similarities to metastatic renal or adrenal carcinoma and, rarely, melanoma may be striking (see Fig. 38-12B).

An uncommon **pleomorphic (giant cell) pattern**, constituting less than 1% of hepatomas, is also recognized. The tumor is characterized by the presence of **many noncohesive, multinucleated giant cells with small nuclei**, which resemble **osteoclasts**. The tumors usually contain areas of conventional HCC (Kuwano et al, 1984; Hood et al, 1990) (see Fig. 38-15C).

Cytology

As emphasized above, the cytologic interpretation of liver aspirates is of critical significance in the diagnosis of liver neoplasms, and therefore in the clinical handling of patients. In general, the cytologic presentation of HCC on the aspiration smear closely reflects the degree of differentiation of the primary tumor. The task is not always easy at both ends of the diagnostic spectrum. On the one hand, it may be difficult to differentiate cirrhotic livers or other benign disorders from well-differentiated HCCs (Figs. 38-8, 38-9, and 38-10); on the other hand, poorly differentiated liver tumors, composed of cells that have lost the features of hepatic origin, often mimic metastatic tumors (see Fig. 38-12C,D).

Well-Differentiated Hepatomas

The common **well-differentiated HCCs** are by far the **most difficult to identify** because of the similarity of tumor cells to benign hepatocytes. Still, certain features of these tumors are helpful in their recognition.

In aspirated samples, the well-differentiated HCCs usually yield an abundant population of tumor-derived hepatocytes, which occur singly and in large clusters. Quite often, the hepatocytes are somewhat **smaller** and show **less variability in size** than normal; these features are not easily reproducible among observers (Figs. 38-8 and 38-9). Also, the presence of **large nuclei and nucleoli, and intranuclear cytoplasmic inclusions is not a reliable criterion of cancer**, because these features may also be observed in normal hepatocytes and in cirrhosis. Intranuclear cytoplasmic inclusions may also be observed in some metastatic tumors, notably malignant melanomas (Figs. 38-8, 38-9, and 38-10).

The features that are helpful in the diagnosis of this group of hepatomas are described below:

- The **absence of bile duct cells**, inflammation, or necrosis in the sample. The presence of bile duct epithelium, derived from adjacent normal or cirrhotic liver, may lead to an erroneous false-negative report.
- The presence of approximately spherical **clusters of hepatocytes** of various sizes, surrounded by an **outer layer of endothelial cells or capillaries** (Figs. 38-10C and 38-11A-C). This very helpful feature is particularly evident in the common **trabecular variant of HCC, and is virtually never observed in benign samples** or in metastatic tumors (Pitman and Szyfelbein, 1995). This feature is also observed in tissue sections wherein clusters of

tumor cells are separated from each other by capillaries (Fig. 38-11D).

- The presence of numerous nuclei stripped of cytoplasm ("**naked**" nuclei) with conspicuously large nucleoli of irregular shapes (Figs. 38-10A,B and 38-12A). This feature, which was first described by Pedio et al (1988), reflects the **fragility of the cytoplasm of tumor cells** that are damaged during smear preparation (Fig. 38-12B). This feature is commonly observed in **clear-cell hepatomas**.
- **The formation of bile by tumor cells** (Fig. 38-13B-D). This feature is less helpful in direct smears than in **metastatic deposits** (e.g., in lung metastases that may be recognized by **bile-tinged sputum**). In direct, rapidly fixed smears, **bile accumulation may be observed in the cytoplasm of tumor cells**, sometimes in the form of tiny

P.1403

canaliculi that can be visualized with special stains. An important **caveat** is the presence of bile in normal hepatocytes and accumulation of bile in obstructive jaundice, which can be caused by numerous factors, including metastatic tumors. The latter event may lead to diagnostic errors (see Fig. 38-22B,C).

Figure 38-10 Cytologic features useful in recognition of well differentiated hepatocellular carcinoma. *A* (Diff-Quick) and *B* (Papanicolaou) showing numerous dispersed "naked" nuclei of variable sizes. Remnants of cytoplasm and prominent nucleoli are shown. *C*. An approximately spherical cluster of hepatocytes with a sharply demarcated surface lined by endothelial cells (MGG stain). Well differentiated trabecular hepatocellular carcinoma, corresponding to *A*, *B*, and *C*.

Poorly Differentiated HCCs

Poorly differentiated HCCs are easily recognized as malignant, but their hepatic origin may be difficult to document in the aspirated sample. The aspirates contain **tumor cells** with transparent cytoplasm, often of **variable size**, with prominent **large nuclei** and multiple and sometimes **huge nucleoli** (Koss et al, 1992) (see Fig. 38-12C,D). Some cells or cell clusters may **resemble hepatocytes**, and may show some of the features characteristic of well-differentiated hepatomas, as discussed above. In such cases, a tentative diagnosis of HCC

may be ventured, provided that it is supported by clinical and biochemical data, such as a **marked elevation of AFP in serum**.

Fibrolamellar Carcinoma

The cytologic features of fibrolamellar tumors were described by Davenport (1990) in two cases, and by Perez-Guillermo et al (1999) in six cases. The smears contained dispersed **large cancer cells with abundant, granular cytoplasm, thus resembling oncocytes**. Hyaline cytoplasmic inclusions (pale bodies) were observed in some cells. The nuclei and nucleoli were very large. Fragments of connective tissue, sometimes in intimate contact with tumor cells and corresponding to tumor lamellae, were observed in all cases. In the Perez-Guillermo study, the tumor cells and their nuclei and nucleoli were shown to be **larger** in comparison with cells of the common type of HCC, and the differences were statistically significant. Similar tumor cells were observed in a metastatic fibrolamellar carcinoma by Sarode et al (2002). Our experience with this tumor type is limited to an aspirate from a 30-year-old female who presented with a 15-cm mass in the left lobe of the liver, with no clinical evidence of cirrhosis or hepatitis. The FNA was considered to be diagnostic of the disease (Fig. 38-14A-C).

Pleomorphic Hepatoma with Giant Cells

Cytologic experience with the very uncommon pleomorphic hepatomas with giant cells is very limited. We have observed one such example (Fig. 38-15A-C) in which numerous very large tumor cells, some with multiple small nuclei resembling osteoclasts, were intermingled with cells of conventional-type HCC (Koss et al, 1992).

Pseudoglandular (Acinar) Type of HCC

Pseudoglandular (acinar) tumors are uncommon tumors that shed cuboidal or columnar cancer cells that **cannot be differentiated from metastatic adenocarcinomas**, particularly those of gastrointestinal tract origin. The clinical presentation and the absence of mucin are sometimes helpful in the diagnosis.

P.1404

Figure 38-11 Trabecular pattern of HCC. A,B,C. The smears show cohesive spheres of

hepatocytes surrounded by endothelial cells forming a sharp edge of clusters. This cytologic presentation is diagnostic of HCC (Diff-Quick [A] and Papanicolaou [B,C]). *D.* Tissue section of corresponding tissue. The patient was a 47-year old male with paraspinal metastasis and an α -FP level of 35,500 ng/ml.

Summary of the Cytologic Features of HCCs

The dominant cytologic features of HCCs, with their corresponding histologic patterns, are summarized in Table 38-2. However, these patterns may coexist in a given tumor, and cytologic sampling may not capture more than one or two of the characteristic features.

Immunohistochemical Studies

At times it can be difficult to cytopathologically distinguish between poorly differentiated HCC and metastatic adenocarcinoma without the help of ancillary studies. Numerous antibodies have been developed and much has been written about the utility of immunohistochemical stains (Christenson et al, 1989; Hurlimann et al, 1991; Van Eyken et al, 1993; Minervini et al, 1997; Porcell et al, 2000). Polyclonal CEA (pCEA) positivity in a canalicular pattern was the old gold standard for the immunohistochemical diagnosis of HCC. Recently, a monoclonal mouse anti-human “**hepatocyte**” antibody (OCHE1E5, hepatocyte paraffin 1, Hep par 1; DAKO Corp., Carpinteria, CA), was reported to be present in normal human hepatocytes and expressed in a majority of HCCs, as well as in some gastrointestinal malignancies. This antibody has been tested in cell blocks of FNA of liver, with promising results (Zimmerman et al, 2001; Siddiqui et al, 2002). Conversely, an antibody named “**human epithelial related antigen**” (also called MOC-31; DAKO), has been reported to be negative in HCC but positive in the vast majority of cholangiocarcinoma and metastatic adenocarcinoma cases (Porcell et al, 2000). Table 38-3 summarizes the immunostains that are useful in distinguishing HCC from metastatic adenocarcinoma and cholangiocarcinoma.

Intrahepatic Cholangiocarcinoma (ICC)

Only about 10% to 20% of primary liver cancers are intrahepatic cholangiocarcinomas. The risk factors for HCC (i.e., hepatitis B or C infection, and cirrhosis of the liver) are not applicable to these tumors. ICCs occur in a background of **chronic bile stasis** caused by stones or the liver fluke (*Clonorchis sinensis*). **Caroli's disease** (congenital cystic dilatation of the intrahepatic biliary tree) (Bloustein, 1977) and **primary sclerosing cholangitis or chronic inflammatory bowel disease**, may also lead to ICC, mostly in male patients (Wee et al, 1985). When **Thorotrast** was used for diagnostic purposes, it was also thought to cause ICC (Rubel and Ishak, 1982). Occasionally, this tumor may develop in patients with primary biliary cirrhosis (Marimoto et al, 1999).

The presenting symptoms of ICC are similar to those of HCC, with a few exceptions:

P.1405

Figure 38-12 *A.* Well-differentiated HCC with many naked nuclei and large nucleoli. In the center, the cell cluster has delicate, pink granular cytoplasm, an indication that the naked nuclei are cells that have lost their cytoplasm during smear preparation. Similar phenomenon is seen in direct smears of renal cell carcinoma, clear-cell type (see Fig. 40-8). *B.* Clear-cell HCC. The cytoplasm is finely vacuolated by glycogen deposits. The larger vacuoles store fat. *C.* A poorly differentiated HCC, which often lacks hepatocellular differentiation and mimics metastatic high-grade carcinoma (e.g., from lung or breast). *D.* In a needle core biopsy, a trabecular pattern is identifiable in the tumor shown in *C.*

- Contrary to HCC, which is observed mainly in males, the male-to-female ratio is equal.
- Jaundice is more common.
- There is no elevation of serum AFP.

On imaging of the liver, and on gross examination of resected livers, the tumor is most often observed as a **single large mass** with infiltrating borders (Fig. 38-16A). However, the tumor may also form **multiple smaller nodules** or be **diffuse** and composed of numerous nodules measuring less than 1 cm in diameter. Necrosis or hemorrhage is uncommon. When the tumor nodules are multiple, they are **often mistaken for a metastatic cancer**.

Histology

Most ICCs are **mucus-producing adenocarcinomas** with moderate amounts of densely **fibrotic stroma**. They are morphologically similar to carcinomas arising from the pancreaticobiliary ductal epithelium (see Chaps. 24 and 32). The gland-forming tumor cells are uniform and cuboidal to low-columnar in configuration, with transparent or slightly granular cytoplasm, and ovoid basally placed nuclei (Fig. 38-16B). Bile is not produced by the cholangiocarcinoma cells, but **mucus** can be demonstrated. **A trabecular or solid pattern of growth** may occur, thus simulating HCC. However, the presence of densely fibrotic stroma, rather than intratumor capillary sinusoid vessels, allows for an easy distinction to be made in most cases. As with cancers of the biliary tree, very rare variants of ICC with **colloid (mucinous), signet ring cell, adenosquamous, mucoepidermoid, or sarcomatoid patterns** have been recognized by the World Health Organization (WHO) (Nakanuma et al,

2000). **Combined HCC and ICC** is rare and occurs in less than 1% of tumors (see Fig. 38-18) (Goodman et al, 1985; Maeda et al, 1995). We have seen a case of **well-differentiated squamous cell carcinoma** that arose from the intrahepatic bile duct and presented as a hilar mass in both the fine-needle aspirate and the subsequently resected specimen.

Cytology

Because ICC typically has a densely sclerotic stroma, the smears vary in cell content. The smear pattern is that of an adenocarcinoma with **clusters of cuboidal or columnar cells forming acini or clusters of papillary configuration in a clear background** (Fig. 38-16C,D). The cells are smaller than the malignant hepatocytes in HCC. In any given case, the tumor cells are relatively uniform, with large hyperchromatic or clear nuclei, and hence a high nucleocytoplasmic (N/C) ratio. Although **prominent nucleoli** are seen in some cells, huge nucleoli are distinctly uncommon.

P.1406

Figure 38-13 HCC with prominent intranuclear cytoplasmic inclusion. *A.* Aspiration of a painful rib lesion. *B.* Corresponding biopsy showing compact solid pattern of hepatoma. Note the many intranuclear cytoplasmic inclusions and bile production. *C.* HCC with bile formation. This is uncommon in smears, and is usually seen in a pseudoglandular or acinar pattern of HCC. *D.* Pseudoglandular (tubular or acinar) pattern of HCC. Note the columnar cells forming glands with bile in the lumen.

Figure 38-14 Fibrolamellar HCC. *A.* Clusters of large polygonal cells in intimate contact with elongated strands of connective tissue. *B.* Cell pleomorphism, pink granular cytoplasm, prominent nucleoli, pale body (at 12 o'clock), and small eosinophilic globule (at 3 o'clock) are characteristic of the tumor. *C.* A 15-cm mass was resected from the noncirrhotic liver of a 30-year-old female. Lamellar fibrosis and many eosinophilic hyaline globules are evident.

P.1407

Figure 38-15 Pleomorphic giant-cell variant of HCC. *A.* The presence of many multinucleated giant cells is required for this subclassification. *B.* Note the osteoclast-like giant cell. *C.* Liver biopsy. Pleomorphic (giant cell) pattern. Compare with regenerating nodules in cirrhosis (Fig. 38-3C,D).

De May (1999) reported that extremely well-differentiated cholangiocarcinomas may present as disorderly clusters of bile duct cells with no significant morphologic abnormalities, and may suggest a **bile duct adenoma** or a **hamartoma** of the bile ducts. However, adenomas are subcapsular and small, and usually are an incidental finding; therefore, they differ significantly from ICCs on imaging and clinical presentation.

TABLE 38-2 MAJOR CYTOLOGIC FEATURES OF HCC AND THEIR HISTOLOGIC CORRELATION

Cytology

Histology

Tumor cells closely resemble benign hepatocytes with altered N/C ratio and prominent nucleoli	Very well-differentiated HCC
Clusters of malignant cells, surrounded by a layer of endothelial cells	Trabecular (sinusoidal, plate-like) pattern
Numerous dispersed "naked" nuclei, stripped of cytoplasm with very large irregularly shaped nucleoli	Common in all hepatomas, conspicuous in clear cell pattern
Cohesive groups with cuboidal/columnar cells mimicking adenocarcinoma	Pseudoglandular (acinar) pattern
Dispersed polygonal, pleomorphic large cells with dense pink (oncocytic) cytoplasm, some containing "pale bodies" and fragments of connective tissue	Fibrolamellar pattern
Pleomorphic multinucleated giant tumor cells	Pleomorphic or giant-cell HCC
Malignant hepatocytes and malignant glandular cells	Combined cholangio- and hepatocellular carcinoma

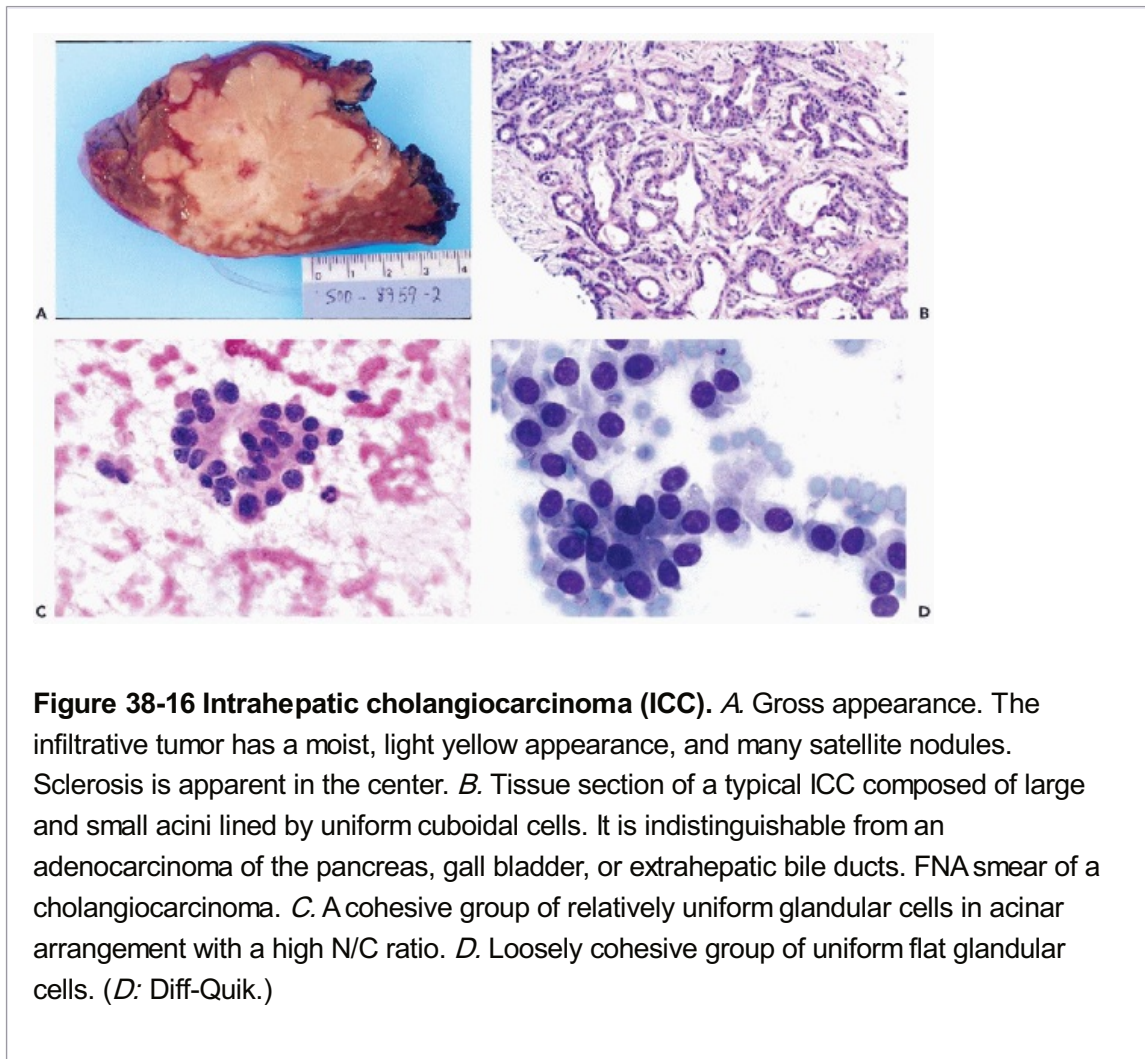

We have seen the FNA smears of a 72-year-old diabetic and hypertensive female with abdominal pain and liver mass. Abundant clusters of elongated bile duct epithelium, some forming small acini with no significant cytologic abnormality, supported the diagnosis of bile duct adenoma (Fig. 38-17A,B). A distinctly different minor population of malignant glandular cells was also seen (Fig. 38-17C). The patient was not a surgical candidate, and a core needle biopsy confirmed the diagnosis of cholangiocarcinoma adjacent to a bile duct adenoma (Fig. 38-17D).

The cytologic presentation of ICC is rarely unequivocally diagnostic of this tumor because of its similarity to the much more frequent metastatic adenocarcinomas, particularly in the presence of multiple tumor nodules. Although subtle differences in the cytologic presentation of certain metastatic cancers (such as of the colon or stomach; see below) may be obvious to very experienced observers, the diagnosis of ICC is a **diagnosis of exclusion** (i.e., the search for other primary tumors is negative). At present, **no specific tumor marker is useful for distinguishing cholangiocarcinoma from other forms of adenocarcinoma.** In contrast, immunohistochemical stains to distinguish

P.1408

ICC from HCC may be helpful. Although most ICCs are positive for cytokeratin-7, cytokeratin-19, carcinoembryonic antigen (Fig. 38-18D), CA 19-9, epithelial membrane antigen, and the antibody MOC-31, only a small fraction of HCCs are positive for these markers, as shown in

Table 38-3.

However, the difference in treatment options and prognoses between metastatic adenocarcinoma and ICC is very important, particularly if the primary tumor is small and resectable. A careful workup of the patient is required, as was recently shown by us in a case of primary, resectable gall bladder carcinoma, mimicking ICC or metastatic cancer, that infiltrated the adjacent liver parenchyma and formed a tumor 5 cm in diameter (Fig. 38-19A-D).

Examples of the cytologic presentation of **combined hepatocellular and cholangiocarcinoma** in FNA are extremely rare. To establish this diagnosis, **two distinct cell populations** (one representing HCC and one representing ICC) must be present side by side. Kilpatrick et al (1993) reported two such cases in which the population representative of HCC stained positively for AFP. In a recent case involving resected combined liver tumors at our institution, a review of the smears revealed only the HCC component in striking acinar arrangements (see Fig. 38-18A-D).

A flow chart (Table 38-4) may be helpful in sorting out diagnostic dilemmas; however, please bear in mind that no such chart can be all-inclusive.

Hepatoblastoma

Hepatoblastoma is the most common primary malignant tumor of the liver in children below the age of 5, although HCCs may also occur. It is twice as common in males as in females (for recent summaries see Stringer, 2000; Stocker, 2001). Most tumors are discovered by palpation,

usually by the child's mother and occasionally by the child, and confirmed by imaging studies. Grossly, the tumors measure 10-12 cm and have smooth or lobulated borders (Fig. 38-20A). Hepatoblastomas **produce AFP**, sometimes at a very high level. A radioisotope-labeled **antibody to AFP** can be used to **stage** the hepatoblastoma before treatment decisions are made. In most cases the treatment is chemotherapy, resection of the tumor, or liver transplantation (Kairemo et al, 2002).

P.1409

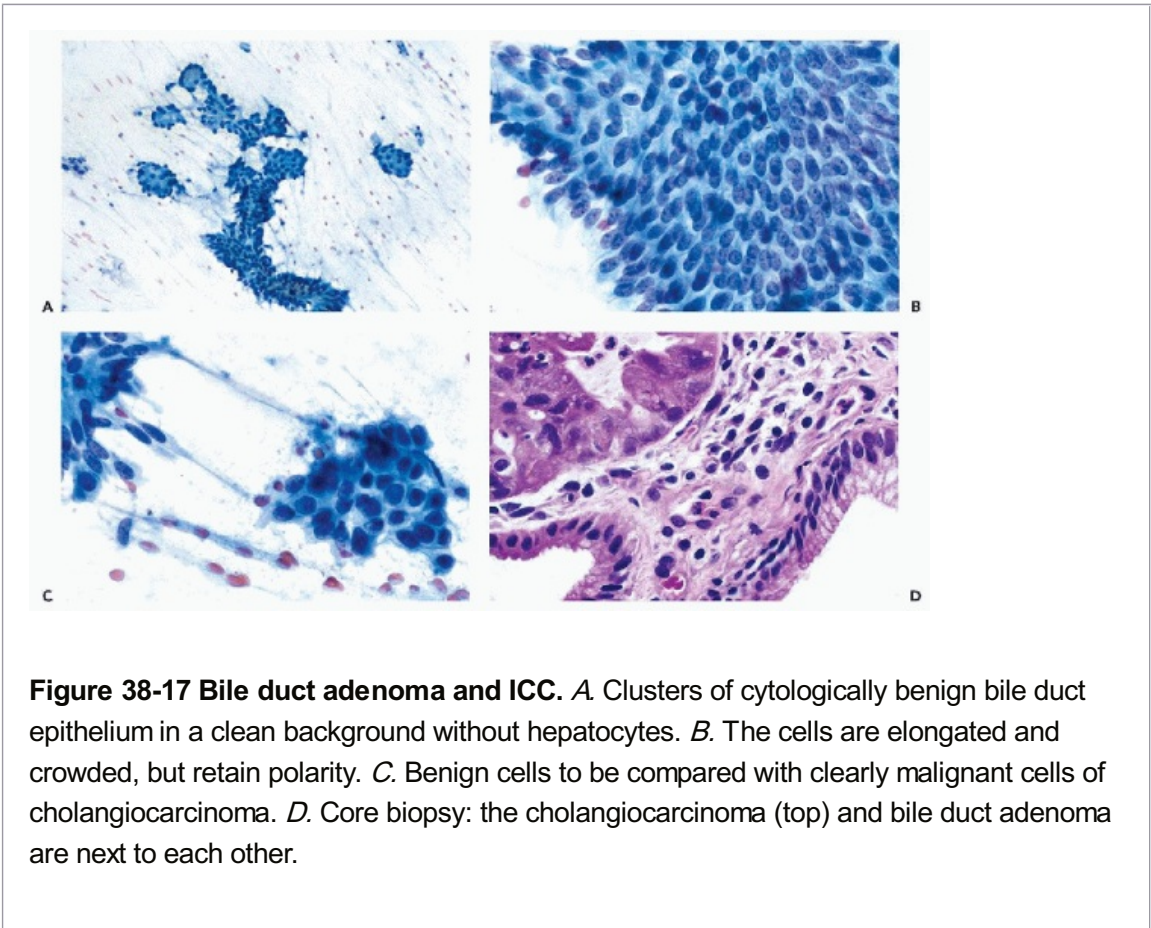

TABLE 38-3 IMMUNOHISTOCHEMISTRY OF HCC VS. METASTATIC ADENOCARCINOMA

Antigen	HCC	ICC/Metastatic Adenocarcinoma★
Hepatocyte (Dako)	Positive (most useful in diagnosis)	Usually negative
Polyclonal carcinoembryogenic antigen (pCEA)	Positive (canalicular pattern)	Positive (diffuse)
Alpha-fetoprotein (AFP)	Positive or negative	Usually negative
Alpha-1-antitrypsin (α-1-AT)	Positive or negative	Usually negative

Cytokeratins 8 and 18 (CK 8 and 18)	Usually positive	Usually negative
Cytokeratins 7 and 19 (CK 7 and 19)	Usually negative	Usually positive
Epithelial membrane antigen (EMA)	Negative	Usually positive
Ber EP4	Negative	Usually positive
CA19-9	Usually negative	Usually positive
Human epithelial related antigen (MOC-31)	Negative	Usually positive

★ The immunohistochemical features of intrahepatic cholangiocarcinoma (ICC) and metastatic adenocarcinoma are similar.

P.1410

Figure 38-18 Combined HCC and ICC. FNA of a solitary 6-cm mass in the liver of an 86-year-old male with no other known primary tumor. *A.* Cohesive groups of cuboidal/columnar cells with pink granular cytoplasm and intranuclear cytoplasmic inclusions (INCI) is consistent with a diagnosis of HCC. *B.* A Pap-stained preparation shows a striking acinar arrangement of smaller cancer cells. *C.* Tissue section of a pseudoglandular (acinar) HCC. Note the presence of intranuclear cytoplasmic inclusion for carcinoembryonic antigen (CEA). *D.* Cholangiocarcinoma in the adjacent field. The tumor cells were focally positive CEA.

Histology

In keeping with other “blastomas” of pulmonary or renal origin, the hepatoblastomas show a mixture of cell types. The **epithelial components** of the tumor may resemble small hepatocytes (**fetal type**) (Fig. 38-20D) or they may be spindly and not otherwise differentiated (**embryonal type**). The **mesenchymal components** may represent a variety of tissue types, ranging from loosely structured connective tissue to cartilage. Occasionally, the tumor contains an **anaplastic component of small cancer cells**, resembling other **small blue cell tumors of childhood**. The latter histologic pattern apparently confers a poor prognosis (Haas et al, 2001). **Extramedullary erythropoiesis** is commonly observed within the tumor. As is often the case with neoplasms of childhood, hepatoblastomas may show **specific chromosomal abnormalities**. Gains in chromosome 2q and 20, and rearrangement of chromosome 1 have been reported (Ali et al, 2002).

Cytology

Aspiration cytology generally correlates with the subtype of the tumor within the sampled area. The **fetal epithelial type** (33%) is quite similar to well-differentiated HCC (Fig. 38-20B,C) except that the cells are dispersed, smaller than cells of HCC, and fairly uniform, with a higher N/C ratio. The **embryonal type** is composed of small, poorly differentiated, spindly malignant cells. Approximately 50% of hepatoblastomas are mixed epithelial and mesenchymal tumor cells arranged in three-dimensional clusters, loose sheets, cords, rosette-like structures, and occasionally pseudopapillae. **Metaplastic elements** (e.g., bone, cartilage, or muscle) may also be present in hepatoblastomas (Uš-Krasovec et al, 1996). **Extramedullary hematopoiesis** is recognized by the presence of megakaryocytes (Bhatia and Mehotra, 1986; Dekmezian et al, 1988). The principal points of a **differential diagnosis** of fetal-type hepatoblastoma include a bonafide HCC. The mixed types of this tumor must be differentiated from the very rare **benign mesenchymal hamartoma** of liver (al-Rikabi et al, 2000).

The **anaplastic type of hepatoblastoma** is cytologically similar to other small blue cell tumors of childhood, such as neuroblastoma, embryonal rhabdomyosarcoma, Wilms' tumor, or Ewing's sarcoma, which may be **metastatic to the liver** (Perez, 1994). Clinical and imaging data will usually solve the problem of differential diagnosis.

P.1411

Figure 38-19 Mucinous adenocarcinoma of the gallbladder. *A.* Smear of malignant glandular cells in a three-dimensional cluster. *B.* Mucinous adenocarcinoma cells with prominent nucleoli. The tumor initially was thought to be metastatic to the liver. *C.* Core needle biopsy of the same tumor was also consistent with metastatic adenocarcinoma. *D.* Resected segment of the liver shows a gall bladder carcinoma directly infiltrating the liver (see text).

VERY RARE PRIMARY TUMORS

Primary Carcinoids

As a rule, carcinoids and other morphologically similar **endocrine tumors** in the liver are metastatic from the intestinal tract or the pancreas, and sometimes from other primary sites. However, in rare cases, no other primary tumor can be found and it must be assumed that the tumor is primary in the liver. Iwao et al (2001) reviewed 53 such cases. Such tumors may be hormonally active (Furrer et al, 2001), and some **may be cystic** (Dent and Feldman, 1984; Thompson et al, 1984).

Primary liver carcinoids are **morphologically identical to primary carcinoids in the lung** (see Chap. 20) or the intestine (see Chap. 24), and are composed of **anastomosing strands of small cells that occasionally form rosettes**. The endocrine nature of such tumors can be documented by **electron microscopy or any number of special stains** (see Chap. 45). Exceptionally, liver carcinoid may be associated with adenocarcinoma (Hidaka et al, 2000).

The cytologic presentation of these tumors is also characteristic: **small epithelial cells of similar sizes** form solid or glandular aggregates, or occur singly. The cells have scanty but well-preserved cytoplasm and **finely granular “salt and pepper” nuclei** that are often located at the periphery of the small cells, giving them a **plasmacytoid configuration**. The **nucleoli** are usually very small. Through the courtesy of Dr. Jennifer Alexander in Kingston, Jamaica, we have seen a case of **cystic primary carcinoid of liver** in a 55-year-old man with a tumor that grew slowly over a period of 4 years. The aspirate, which was diagnostic of the tumor, was obtained from the wall of the cyst after several unsuccessful attempts were made to establish the diagnosis from the fluid content of the cyst (Fig. 38-21A,B). Gupta et al (2000) observed

primary liver carcinoids in three of 10 patients (the remaining seven patients had other primary tumor sites). Carcinoids of the liver are amenable to aggressive treatment, with excellent results.

Primary Sarcomas

Angiosarcoma

Clinical and Epidemiologic Data

Angiosarcoma is the most common primary sarcoma of the liver. It occurs predominantly in patients past the age of 60 (and hence in the same age group as for HCC). Although most hepatic angiosarcomas are idiopathic, approximately one quarter are strongly associated with exposure to **toxic**

P.1412

agents, particularly **polyvinyl chloride**, **Thorotrast**, and **inorganic arsenic** (Falk et al, 1981). Rosenthal et al (2000) added **cyclophosphamide** to the agents linked with hepatic angiosarcoma. Manifestations of **thrombocytopenia** and **disseminated intravascular coagulation** are common in angiosarcomas. **Angiography** showing multiple vascular lesions in the liver may be diagnostic of this tumor, and is therefore superior to other imaging modes.

TABLE 38-4 ALGORITHMIC FLOW CHART FOR SPACE-OCCUPYING LESIONS OF LIVER

Cytomorphology	Possible Diagnosis
Normal hepatocytes	Normal liver (lesion missed on sampling).
Scanty bile duct epithelium	FNH
Scanty fibrous stroma	Cirrhotic nodule
Normal appearing hepatocytes	Well-differentiated HCC
Strings of endothelium	Liver cell adenoma (need radiologic and clinical correlation)
No bile duct epithelium	
Cells in clusters or trabeculae with smooth edges surrounded by endothelial cells	Classic HCC
Single cells with high N/C ratio	
Polygonal cells similar to hepatocytes	Less differentiated HCC
High N/C ratio with central nuclei	

Many stripped nuclei with huge nucleoli	
Adenocarcinoma	Consider ICC
95% are metastatic adenocarcinoma	
Look for clues ^a (make a brilliant diagnosis)	
Small-cell malignant tumor ^b (Age of patient is of diagnostic importance)	Pediatric blastomas
	Small-cell carcinoma of lung
	Pancreatic endocrine tumors
	Lymphoma, metastatic small-cell tumor of childhood, particularly neuroblastoma
Acellular smears (blood only)	Hemangioma/angiosarcoma
Look for fragments of stroma	
Fluid/mucin/glandular cells	Cystadenoma
	Ciliated foregut cyst
Histiocytes/bile duct epithelium	Cysts
Polymorphonuclear leukocytes (PMN)	Abscess
Note: Consult text for cytologic criteria.	
^a See Tables 38-5 and 38-7.	
^b Almost always metastatic. See Table 38-6.	

Histology

Well-differentiated angiosarcoma forms bizarre vascular channels of various sizes, lined by **plump endothelial cells with variable degrees of atypia**. In some cases, such endothelial cells line **preexisting liver sinusoids** with intact liver cell cords and may be very difficult to diagnose in a core biopsy. High-grade angiosarcoma appears as a fully malignant **spindle cell tumor with rudimentary vascular channels**. Factor VIII staining will usually confirm the

vascular nature of these tumors.

Cytology

Because of the risk of exsanguinating hemorrhage, an aspirate is performed only in cases in which the diagnosis is not suspected. The number of patients whose tumors have been aspirated is vanishingly small and the descriptions of the cytologic findings vary (Soslow et al, 1997; Liu and Layfield, 1999; Boucher et al, 2000; Nguyen and Husain, 2000). DeMay (1999) described a malignant spindle cell tumor with **pleomorphic single cells and whorls of cells** in a very bloody, sometimes necrotic background. This is certainly a

P.1413

fortuitous and exceptional presentation of this neoplasm. Suslow et al (1997) described “**epithelioid cells with intracytoplasmic lumens**” in a case diagnosed as **hemangioendothelioma. Metastatic spindle cell tumors (most often leiomyosarcomas, but also hemangiomas and fibrolamellar carcinomas)** are the common points of differential diagnosis (Guy et al, 2001). One of the principal difficulties with the aspirates is the abundance of blood and the **scarcity of tumor cells**. In our modest experience, the FNA smears contain a small number of spindly cells of questionable diagnostic value. Unless the clinical and imaging data support the diagnosis of angiosarcoma, the cytologic opinion should be worded with caution. See also Chapter 35.

Figure 38-20 Hepatoblastoma in a 4-year-old girl. A. The central scar is not characteristic. B,C. Aspiration smear with an epithelial component quite similar to moderately differentiated HCC in adults. D. Tissue pattern corresponding to B and C.

MALIGNANT LYMPHOMA

The liver is commonly involved by metastatic malignant lymphomas and Hodgkin's disease, but very rarely is it the site of a primary lymphoma (usually of the large B-cell type). The cytologic diagnosis requires an extensive diagnostic workup. A touch preparation of a core biopsy or a cytologic preparation of residual material from the needle may enhance the diagnosis, as was reported many years ago (Sherlock et al, 1967).

METASTATIC TUMORS TO THE LIVER

In Europe and North America, the ratio of metastases to primary hepatic tumors is 40:1 (Berge and Lundberg, 1977; Pickren et al, 1982). With the recent increase of primary hepatomas in large medical centers that offer partial hepatectomies and liver transplantation, the ratio of metastatic carcinoma to primary HCC is 3:1 (Hertz et al, 2000). As stated previously, a malignant tumor observed in an otherwise normal liver is **metastatic until proven otherwise** (Melato, 1989; Nzeako, 1996).

Origin of Metastases

Most metastatic neoplasms to the liver are carcinomas, most of which are adenocarcinomas of various origins. Other types of metastases (e.g., lymphomas and sarcomas) are much less common. The lung, colon, pancreas, breast, and stomach are the most common primary sites of hepatic metastases, but malignant tumors from almost any site can at times metastasize to the liver (Craig et al, 1989) (Table 38-5).

Elevated levels of **serum alkaline phosphatase, and multiple nodules on imaging of the liver** are the characteristic findings. However, **single metastases** may also occur, particularly with colorectal carcinoma, carcinoid tumors, and renal cell carcinomas (Pickren et al, 1982). In most

P.1414

cases, **the purpose of FNA** is to confirm the diagnosis of metastases from a **known primary site**. Surprisingly, in a significant number of such procedures, FNAs have been performed following a request to "rule out malignancy," with no comment regarding a known primary, even though with further scrutiny of the patient's chart and database, a source of the tumor should have been discovered. A review of prior histologic or cytologic material, if available, is very helpful to confirm the identity of the tumor.

Figure 38-21 Carcinoid tumors in liver. *A,B.* Cystic primary carcinoid of liver. *A.* Uniform small cells with scanty eosinophilic cytoplasm, forming small gland-like structures. *B.* Tumor cells anchored around a capillary. Benign hepatocytes at the left lower corner (cell block of FNA). *C,D.* Metastatic carcinoid with occult ileal primary. The smear shows uniform well-preserved small cells in a cohesive group without nuclear molding or single-cell necrosis,

which distinguishes the carcinoid from metastatic small-cell carcinomas. *D. Histology.* A submucosal carcinoid was found in the small intestine (ileum).

TABLE 38-5 SITES OF ORIGIN OF HEPATIC METASTASES IN 1,151 AUTOPSIED PATIENTS

Site	Percentage of Patients
Lung	24.8
Colon	15.7
Pancreas	10.9
Breast	10.1
Stomach	6.1
Unknown	5.1
Ovary	4.1
Prostate	3.6
Gallbladder	3.3
Cervix	3.0
Kidney	3.0
Melanoma	2.2
Miscellaneous origin	8.1

(Data from Craig et al. Tumors of the Liver and Intrahepatic Bile Ducts. Washington, DC, AFIP, 1989.)

However, in a substantial proportion of patients (which varies from 10% to 40%, depending on the institution), the liver lesion may be the **first manifestation of disease**, and FNA is **used not only to diagnose cancer but also to attempt to recognize the site of origin**. Careful examination of the aspirate may often limit the search for the correct primary site to a few organs. Although in general the **prognosis of patients with metastatic cancer to the liver is**

dismal, there are **exceptions** to this rule, notably in cases of **malignant lymphoma, small-cell tumors of childhood**, and **endocrine tumors**, such as carcinoids (see below). Brilliant and life-saving diagnoses can often be made based on smear background and careful analysis of the morphology of the cells, even without the benefit of special stains. **Additional smears**

P.1415

or cell blocks of aspirated material are very helpful if **special stains and immunostains** are required to support the identity of the hitherto unknown primary tumor.

The simplest analysis of evidence is based on **cell size, shape, cytoplasmic and nuclear characteristics, and the presence or absence of prominent nucleoli**. The smear is then categorized as one of several types of tumors, as listed below. These categories can then be analyzed in the light of the **patient's age and sex, clinical history, laboratory findings, and more refined cytomorphologic criteria**. **A series of flow charts should facilitate further analysis of the various categories** (Tables 38-6, 38-7, 38-8 and 38-9). The following broad categories may be recognized:

- **Small-cell tumors**
 - Differentiated (with specific features)**
 - Undifferentiated (with no specific features)**
- **Large-cell tumor**
 - Most likely of epithelial origin**
 - Carcinoma with glandular features**
 - Carcinoma with squamous features**
 - Carcinoma with unique recognizable features**
 - Not likely to be of epithelial origin**
 - With or without recognizable features**
- **Spindle cell tumor**
- **Tumors with unusual or bizarre features**

TABLE 38-6 DIFFERENTIATED AND UNDIFFERENTIATED SMALL-CELL TUMORS IN LIVER			
Cytologic Features	Age	Helpful Ancillary Studies	Diagnosis/Primary Site
Cohesive clusters of small cells			
Nuclear molding, cell necrosis	Older patients	Cytokeratin (positive)	Small-cell (oat cell) carcinoma
Small cells	Infants and	Neuroendocrine	Neuroblastoma

forming rosettes background neuropil (pink fibrillar material)	children	markers (positive)	
Mixture of undifferentiated small (blastemic) cells and columnar cells forming tubules	Children	Vimentin- and keratin-positive	Wilms' tumor (nephroblastoma)
Monotonous, small round cells micronucleoli, no cell molding	Adolescents and young adults	CD99 and vimentin (positive) PAS- positive in cytoplasm	Ewing's sarcoma
Irregular small spindly cells, and rarely strap cells	Infants and children	Vimentin, desmin and myoglobin positive	Embryonal rhabdomyosarcoma/retroperitoneal, genitourinary, head and neck
Isolated or noncohesive small cells, nuclear abnormalities	Any age	Lymphocyte common antigen (LCA) positive	Lymphoma
Very uniform round or oval-shaped small cells, singly or in clusters, salt and pepper nuclei	Adults	Neuroendocrine markers (positive)	Carcinoid tumors Usually metastatic; rarely primary in liver

Small-Cell Tumors

A flow chart for the diagnostic analysis of small-cell tumors is shown in Table 38-6. The differential diagnoses should also be considered in the light of the clinical presentation and the known natural **history of the tumor**. For example, the two most common undifferentiated small-cell tumors in the pediatric age group are neuroblastomas and Wilms' tumors.

Neuroblastomas commonly metastasize to bone and relatively rarely to liver, whereas Wilms' tumors often metastasize to liver and rarely to bone. Finally, **immunocytochemical stains** may secure a specific diagnosis.

Of special practical interest is the diagnosis of a **metastatic endocrine tumor, such as a carcinoid, in the absence of a known primary site**. The cytologic presentation of this tumor is discussed above. If necessary, a positive stain for endocrine markers, such as chromogranin, will help in establishing the diagnosis. In a few such cases, **an occult primary tumor** could be localized in the small intestine (see Fig. 38-21C,D). Because aggressive treatment of carcinoids may successfully extend good quality of life for several years, the correct identification of such metastatic tumors is of great clinical value.

Large-Cell Tumors

Similar **flow charts** have been devised for glandular, squamous, and spindle cell tumors (see Tables 38-7, 38-8 and 38-9).

P.1416

These flow charts should guide the thought process of all cytopathologists, and are an effective tool for establishing specific cytopathologic diagnoses of malignant and benign tumors.

TABLE 38-7 LARGE-CELL METASTATIC EPITHELIAL TUMORS WITH GLANDULAR FEATURES

Cytologic Features	Age/History	Helpful Ancillary Studies	Diagnosis/Primary Site
Linear strips of columnar cells with elongated nuclei and ruby-red nucleoli in a necrotic background	Elderly/colon cancer	Colonoscopy in the absence of prior history	Colonic adenocarcinoma
Generally uniform polygonal cells with high N/C ratio in groups, chains or single files, sometimes with cytoplasmic inclusion of mucin	Adult female/breast cancer	Estrogen receptor (ER)/progesterone receptor (PR) positive	Breast carcinoma, ductal type
Pleomorphic glandular clusters and single cells, prominent nucleoli, transparent cytoplasm and large mucin vacuoles in some cells	Adult smoker/lesion in the lung or hilum	Thyroid transcription factor-1 (TTF-1) positive	Lung cancer, adenocarcinoma or large-cell carcinoma
Signet ring cells and	Adult male or	None unique	Gastric carcinoma,

or syncytial clusters of mucin producing tumor cells	female/upper GI symptoms		often of linitis plastica type
Syncytial clusters, uniform nuclei, abundant mucinous cytoplasm	Elderly/single mass in gallbladder bed	None dependable	Consider gallbladder carcinoma rarely intrahepatic cholangiocarcinoma (ICC)
	Elderly/multiple nodules	None dependable	Well-differentiated pancreatic carcinoma
Uniform polygonal to pleomorphic single cells with prominent nucleoli, intranuclear cytoplasmic inclusions, thick cytoplasm, sometimes with pigment	Usually adult/history of melanoma	HMB-45 melanosome S-100 protein positive	Malignant melanoma
Single and loosely cohesive round or ovoid uniform cells, pink granular cytoplasm and prominent nucleoli (hepatocytoid adenocarcinoma)	Adult with multiple lesions/history of stomach, ovary, or breast cancer	Negative alpha-fetoprotein (AFP) and Hepar (hepatocyte) immunostains negative	Metastatic gastric, ovarian, or breast cancer mimicking hepatocellular carcinoma (HCC)
The table is simplified for the sake of brevity. Most metastatic tumors of other origins to the liver are adenocarcinoma or have a glandular appearance.			

Some metastatic carcinomas can be recognized in smears because of the morphologic features of cancer cells.

Colon Cancer

In most instances, patients with metastatic colon cancer have a history of treated disease, and the liver aspirate is performed to confirm the identity of the tumor. Metastatic colonic carcinoma, a frequent source of liver metastases, can be recognized in FNA smears in many cases because of **tall columnar cancer cells that are often arranged in linear strips** (Fig. 38-22A). The smears have a **necrotic background**, which is best seen in direct smear

preparations. Quite often, the material secured from the liver by the radiologist spreads like peanut butter on the slides. However, we have seen **exceptions to this rule**. In a case of **occult colonic carcinoma** with obstructive jaundice, the cancer cells contained bile and were mistaken for a primary HCC (Fig. 38-22B,C).

Breast Cancer

In most instances, the primary site of the tumor is known and the liver is aspirated to verify the tumor type involved. Metastatic ductal adenocarcinomas rarely show specific cytologic features, and are usually reported as “adenocarcinoma consistent with breast origin.” Large ductal carcinoma cells may have eosinophilic cytoplasm, and may **mimic HCC**. Sometimes the cancer cells form **chains or “single files”** that are more often seen in lobular cancers than in other metastatic tumors. In some instances, however (mainly in **lobular, but sometimes also in ductal cancers**), small cancer cells with **cytoplasmic inclusions of mucin (target or magenta cells)** may be observed. These cells are **characteristic of mammary carcinoma**, and allow a definitive cytologic diagnosis to be made. For further description of these cells, see **Chapters 26 and 29**. In breast cancer, the primary tumor is often available for review and comparison with the cytologic pattern.

P.1417

TABLE 38-8 LARGE-CELL METASTATIC EPITHELIAL TUMORS WITH SQUAMOID FEATURES

Cytologic Features	Age/History	Helpful Ancillary Studies	Diagnosis/Primary Site
Highly keratinizing and pleomorphic flat tumor cells with necrosis and inflammation	Elderly smoker, drinker, often male/lung, larynx, oral, or esophageal cancer	Unnecessary	Metastatic lung, esophagus, or head and neck tumors, rarely bile duct carcinoma
Combination of single, pleomorphic, keratinized and undifferentiated clusters of uniform cells with rigid cytoplasm and prominent nucleoli	Elderly smoker/lung or esophageal lesion	Unnecessary	Metastatic squamous cell carcinoma: lung, esophagus, or bladder
Usually nonkeratinizing uniform groups with jagged outline and single squamous	Adult or elderly female/carcinoma of lower genital tract (cervix, vagina, or vulva) or history of	Unnecessary	Metastatic epidermoid carcinoma of gynecologic or urothelial origin

cancer cells

bladder tumor

Rare sources of metastatic squamous cell carcinoma are the anus and penis.

TABLE 38-9 METASTATIC TUMORS WITH SPINDLE CELL FEATURES

Cytologic Features	Age/History	Helpful Ancillary Studies	Diagnosis/Primary Site
Spindle-shaped cells isolated and in fascicles with cigar shaped nuclei	Adult/submucosal gastrointestinal tumor	C-kit positive Actin and myosin positive	Gastrointestinal stromal tumor (GIST) Leiomyosarcoma
Polygonal uniform small to medium sized cells with prominent nucleoli	Adult/submucosal gastrointestinal tumor	C-kit positive	Epithelioid GIST
Loose aggregates or syncytial tissue fragments and single epithelial type elongated pleomorphic cells	Adult/synchronous or prior known carcinoma of lung, breast, etc.	Keratin positive, Hepar negative	spindle cell (metaplastic) carcinoma of kidney, lung, breast, and rarely other organs
Ovoid to elongated bare nuclei with salt and pepper chromatin	Adult/atypical carcinoid	Chromogranin and other endocrine markers positive	Carcinoid tumor of lung, pancreas, etc.
Pleomorphic single cells and whorls of cells in a very bloody and necrotic background	Elderly/multiple vascular lesions on angiography	Positive endothelial markers	Primary angiosarcoma of liver

Rare sources of metastatic spindle cell tumors (e.g., thymoma (CK+, background lymphocytes), malignant peripheral nerve sheath tumor (S-100+), and other soft-tissue

sarcomas, including malignant fibrous histiocytoma) are not listed.

P.1418

Figure 38-22 Metastatic colonic adenocarcinoma to liver. *A.* Note a strip of columnar cancer cells against a background of necrosis, characteristic of this tumor. *B.* Occult colonic cancer. Cancer cells containing bile, initially diagnosed as HCC. *C.* Biopsy of occult colonic carcinoma, corresponding to *B.*

Lung and Urothelial Cancers

With the exception of small-cell (oat cell) carcinoma, metastatic bronchogenic carcinomas cannot be specifically recognized in smears from liver metastases. However, if the aspirate reveals an epidermoid carcinoma, lung (and urothelial) carcinomas are prime suspects. The diagnosis is usually established with knowledge of the primary tumor.

Metastatic Neuroendocrine Tumors

Metastatic carcinoids of the lung, pancreas, and small bowel constitute a relatively common group. The tumor cells in aspirate smears are very uniform, dispersed, or loosely cohesive, and have characteristic stippled (salt and pepper) chromatin. Chromogranin and other endocrine stains will clinch the diagnosis. However, the intestinal primary tumors may be difficult to find. Other immunostains for pancreatic polypeptides may be reactive. These are indolent tumors, and the patients can be expected to have prolonged survival, even after metastases are reported. Figure 38-15A,B illustrate a very rare primary carcinoid tumor of the liver.

Metastatic Melanoma

Most metastatic melanomas to the liver are of skin or ocular origin. As a reminder, ocular melanomas may take 20 or more years to form hepatic metastases, resulting in the **“glass eye and protuberant abdomen”** syndrome (see Chap. 41). In most instances of metastatic melanoma, **melanin pigment** is present in cancer cells, allowing for a rapid recognition of the

tumor (Fig. 38-23A). Other features of these tumor cells are discussed in Chapter 26. Still, it has been said that melanoma can mimic any tumor. Figure 38-23B illustrates a case of metastatic melanoma with nuclear grooves and small intranuclear cytoplasmic inclusions, mimicking metastatic thyroid carcinoma.

CLINICAL VALUE OF ASPIRATION BIOPSIES OF THE LIVER

It is usually unnecessary or even unethical to subject patients to the risk of morbidity or mortality from an open liver biopsy without first attempting to perform a harmless percutaneous aspiration biopsy to establish the diagnosis of suspected malignant diseases. A US- or CT-guided percutaneous biopsy with a 22-gauge needle usually provides sufficient tissue for diagnosis, with a minimum risk of bleeding or seeding of tumor cells along the needle tract. In cirrhotic patients with portal hypertension and an increased risk of intraabdominal bleeding, the tissue can be obtained in an angiography suit by a transjugular approach (**transjugular liver biopsy**).

As mentioned above, most (but not all) malignant tumors in the liver, whether primary or metastatic, have a poor

P.1419

prognosis. Although small HCCs are amenable to surgical resection or liver transplantation in symptomatic HCC patients, the 5-year survival rate is less than 5%. However, when curative resection is feasible, the 5-year survival rate may be as high as 40% (Stangle et al, 1994).

Figure 38-23 Metastatic melanoma in liver. *A.* Characteristic appearance of metastatic ocular malignant melanoma showing pleomorphic cells and abundant melanin pigment. *B.* Unusual appearance of metastatic melanoma with nuclear grooves and small intranuclear cytoplasmic inclusions, mimicking thyroid carcinoma. Scanty intracytoplasmic melanin pigment is present. The patient was a 45-year-old female with a remote history of excision of a skin lesion. (*A*: H&E; *B*: Pap stain.)

Nonsurgical treatment methods include percutaneous ethanol or acetic acid injections and percutaneous radiofrequency thermal ablation. HCCs are largely resistant to radioand chemotherapy.

Effective treatments for secondary tumors of the liver are largely unavailable, although new drugs developed to treat metastatic cancers offer some promise. In most cases, disseminated disease is present, which precludes surgical intervention. The exceptions are malignant lymphomas and some small-cell tumors of childhood that can be effectively treated with chemotherapy.

The purpose of this chapter is to emphasize that FNA results must be interpreted in the light of clinical information, laboratory values, and sometimes ancillary studies. This approach will lead to accurate diagnoses and subclassifications for the vast majority of space-occupying lesions of the liver.

THE SPLEEN

INDICATIONS AND METHODS

The purposes of FNA of the spleen are to clarify the causes of spleen enlargement (**splenomegaly**) or to determine the nature of **nodular, space-occupying lesions**.

Some years ago, aspiration of the spleen was a common procedure, particularly in Europe. Moeschlin (1951), a Swiss hematologist, wrote a book about it. In Sweden, Söderström (1979) performed more than 1,000 splenic FNAs without radiologic guidance, and described many disease states that could be identified in smears. In the United States, a few large series of splenic aspirates were performed in the 1950s, primarily to assess patients with hematologic disorders or storage diseases (Block and Jacobson, 1950; Morrison et al, 1951). At the time of this writing (2004), FNA cytology of the spleen is still used extensively throughout the world, but is relatively rarely used in the United States. The limited interest in spleen sampling may result from the extensive use of other diagnostic procedures to clarify the cause of splenomegaly, and the relatively high frequency of splenectomies performed for diagnostic and therapeutic purposes (Kraus et al, 2001). The fear of hemorrhage caused by a tear in the splenic capsule that may require an emergency splenectomy may also be a factor (Silverman, 1993; Zeppa et al, 1994). Another complication is pneumothorax (Caraway and Fanning, 1997). Linsk and Franzén (1989) advised against causing splenic puncture in polycythemia and thrombocytopenia.

Nonetheless, evidence shows that when FNA of the spleen is appropriately performed and interpreted, it is a **valuable diagnostic procedure** (Linsk and Franzén, 1989; Zeppa et al, 1994; Caraway and Fanning, 1997). There are relatively few disorders that are unique to the spleen. Therefore, the purpose of this summary is to briefly describe the most important targets of splenic aspirates.

Most enlarged spleens are palpable, and therefore direct aspiration of this organ rarely requires radiologic imaging (Söderström, 1979). However, most users of the FNA technique today are guided by ultrasound (US) or, rarely, by computed tomography (CT). These imaging techniques are particularly useful for targeting nodular lesions. Civardi et al (2001) advocated the use of FNA and tissue core biopsies for diagnosis.

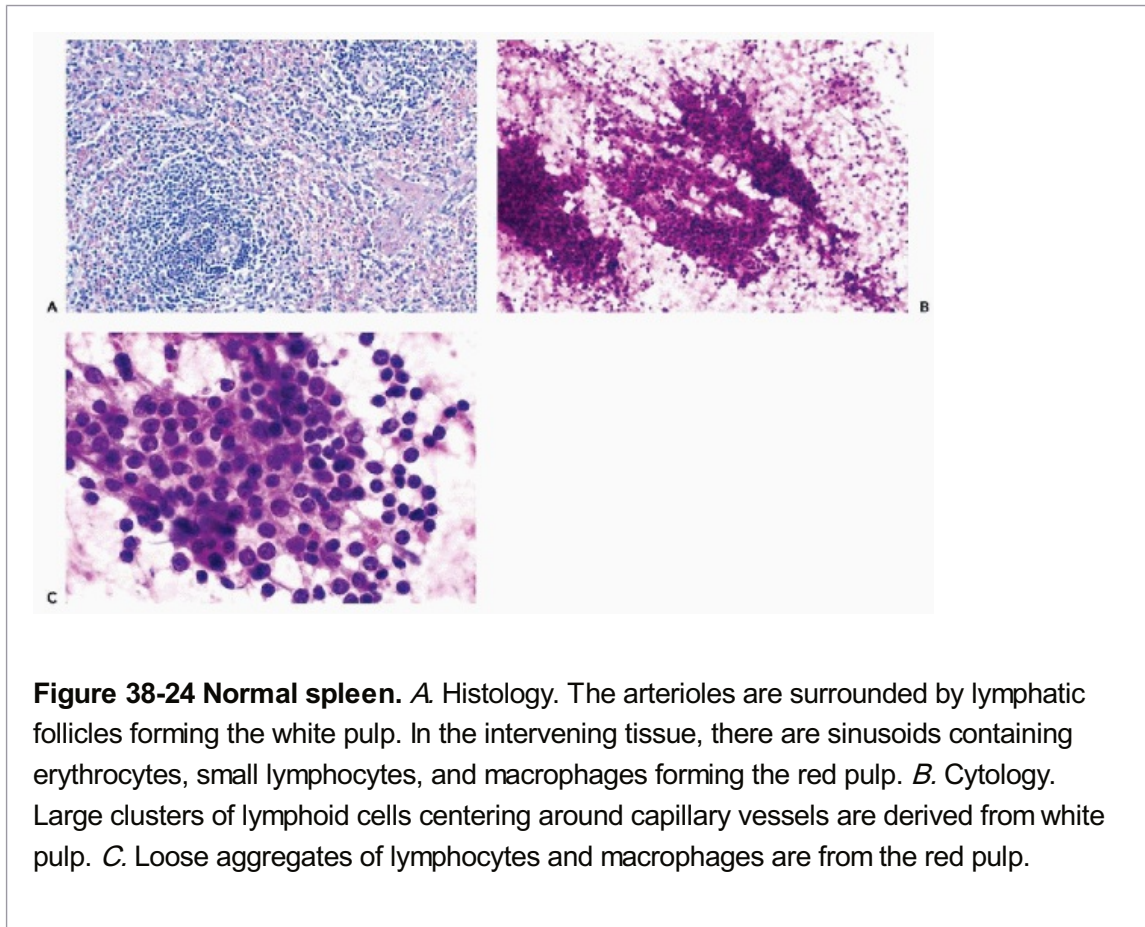

ANATOMY AND HISTOLOGY

The spleen is a **bean-shaped lymphoid organ** that, in a normal adult, measures approximately 12 × 7 × 3 cm and weighs approximately 150 g. The convex surface of the

P.1420

spleen abuts on the left hemidiaphragm and abdominal wall. Its concave surface or **hilus** is the portal of entry and exit of the splenic vessels and nerves, and is adjacent to the gastric cardia, the tail of the pancreas, and the upper pole of the left kidney. The spleen is covered by a **thin but dense connective tissue capsule** surfaced by peritoneum. Finger-like connective tissue trabeculae extend from the capsule into the interior of the spleen. Single or, rarely, multiple small **accessory spleens** are present in about 10% of people. Following a traumatic injury,

dislodged splenic tissue may grow as **implants (splenosis)** on **peritoneal or pleural surfaces**. The **FNA cytology of pleural splenosis** was described by Renne et al (1999).

The spleen is composed of **white and red pulp**. The lymphatic **nodules**, which are distributed throughout the parenchyma, are derived from the **white pulp**. In young individuals, the nodules contain **germinal centers**, which are rich in B-lymphocytes and traversed by a central arteriole (Fig. 38-24A). In older people, the germinal centers are less obvious. Loss of the white pulp may be significant in patients with acquired immunodeficiency syndrome (**AIDS**) (Diaz et al, 2002).

Surrounding the lymphatic nodules is the **red pulp**, a diffuse meshwork containing venous **sinuses (sinusoids)** that carry a large volume of erythrocytes. Small lymphocytes arranged in thin plates (splenic cords), and macrophages with extraordinary phagocytic capability form parts of the red pulp. The principal **function** of the spleen is **to filter out** foreign or useless matter, such as aging or damaged red blood cells, from the bloodstream. The spleen also participates in the **immune response** to all blood-borne antigens. The spleen is believed to be **capable of destroying circulating cancer cells** in **immunocompetent people**, which may explain why the spleen is so **rarely the site of metastatic cancers**.

CYTOLOGY OF NORMAL SPLEEN

Although a normal spleen is never deliberately aspirated, normal components of the spleen are obtained with aspirates of nodular lesions. In principle, the cytology of normal spleen is **similar to that of lymph nodes**. However, the **lymphoid tissue**, which is derived from the white pulp of the spleen, may appear in **large agglomerates of cells centered around branching capillary vessels** (Fig. 38-24B,C). Zeppa et al (1994) stressed that splenic lymphoid cells may form large, multilayered **"terminal aggregates"** that are attached to one end of the capillary

network. The red pulp is represented by lymphocytes and histiocytes.

CAUSES OF SPLENOMEGALY

A broad variety of diseases may cause splenomegaly, as listed below:

- **Infections**, including bacterial, viral, protozoal, and parasitic diseases
- **Congestive splenomegaly**, secondary to portal hypertension, which is **most common in cirrhosis of the liver**, and occasionally occurs in **splenic vein thrombosis**
- **Lymphohematogenous disorders**, such as extramedullary hematopoiesis, lymphomas, hairy cell leukemia, and other forms of leukemia
- **Immunologic-inflammatory disorders**, such as rheumatoid arthritis and systemic lupus erythematosus
- **Metabolic disorders**, such as glycogen storage disease, Gaucher's disease, Niemann-Pick's disease, and mucopolysaccharidoses
- **Miscellaneous causes**, such as cysts, hamartomas, amyloidosis, primary vascular neoplasms, and metastatic tumors

P.1421

Although splenic infarction is quite common, it is usually not associated with splenomegaly.

TARGETS OF ASPIRATION BIOPSY OF THE SPLEEN

Infectious Disorders

Bacterial Infections

The spleen may be enlarged in almost any serious acute bacterial infection with the formation of a so-called **acute splenic tumor**. Such spleens do not require any additional diagnostic workup, and the splenic tumor usually recedes after the underlying infection is treated. Rarely, **splenic abscess** requiring treatment may develop as a consequence of peritonitis. Tikkakoshi et al (1992) described the diagnosis of an abscess by FNA and its subsequent treatment. Dominis et al (1998) described the cytology of an **inflammatory pseudotumor**.

In the developing world, spleen aspirations have a much wider scope. In a study in India, Rajwanshi et al (1999) examined the application of splenic FNA to clarify the **causes of pyrexia of unknown origin**. In about one third of the patients in that study, the splenic aspirate disclosed the presence of **tuberculosis**. Suri et al (1998) also reported the utility of FNA in diagnosing tuberculosis of various organs, including the spleen. For a description of the cytology of FNA aspirates in tuberculosis, see Chapters 19, 29, and 31.

Fungal Infections

Several descriptions of fungal infections that affect the spleen and can be diagnosed by FNA have been reported, including **histoplasmosis** (Kumar et al, 2000), **blastomycosis** (Montes et al, 1998), **aspergillosis** and **candidiasis** (Silverman et al, 1993), and **cryptococcosis** (Mandreker et al, 1998). These organisms are described in detail in Chapter 19.

Parasitic Disorders

Visceral leishmaniasis (from Hindi, *kala-azar* = **black sickness**, so named because of darkening of the skin), which is caused by the parasite *Leishmania donovani* and is

transmitted by sandfly bites, frequently affects the lymph nodes, liver, and spleen. The disease is associated with anemia, leukopenia, and thrombocytopenia, and its diagnosis is based on demonstration of the **tiny parasite in macrophages**. The aspirates of the bone marrow are usually effective in establishing the diagnosis, but in some instances the splenic aspirate is more effective (Sharan and Sinha, 1990; Haque et al, 1993; Mukherjee et al, 1995; Rajwanshi et al, 1999). We have no first-hand experience with these organisms.

Benign Conditions and Tumors

Sarcoidosis

Selroos and Koivumen (1983) and Taavitsainen et al (1987) diagnosed sarcoidosis by splenic FNA. For a description of the cytology of FNA aspirates in sarcoidosis, see Chapters 19, 31, and 32.

Cysts

Cysts of the spleen are uncommon. Most are **pseudocysts** that occur after local destruction of the splenic parenchyma. **Epidermoid cysts, lined by squamous epithelium**, may occur under the spleen capsule and can be aspirated. Two such cases were reported by Nerlich and Permanetter (1991). Predictably, squamous cells with pyknotic nuclei were observed in smears.

Hamartomas

Hamartomas (also known as **splenomas**) are circumscribed lesions of the spleen. They are composed of slit-like **vascular spaces lined by prominent endothelial cells**, and usually contain foci of extramedullary hematopoiesis (Falk and Stutte, 1980; Morgenstern et al, 1985). Kumar (1995) described the histologic and cytologic findings in four such tumors that occurred in patients with anemia and pancytopenia. On abdominal sonography, a diagnosis of malignant lymphoma was suggested. On aspiration biopsy, Kumar observed **large cells that were interpreted as epithelial with abundant cytoplasm, and large, hyperchromatic nuclei, some of which contained large nucleoli. The cells were arranged in clusters, some of which had a papillary configuration**, and were diagnosed as **metastatic carcinomas**. In retrospect, the cells were of **endothelial origin** and were benign. Thus, **splenic hamartoma is an important source of diagnostic error**.

Amyloidosis and Lysosomal Storage Diseases

The spleen often serves as a repository of various abnormal proteins, including amyloid and products of storage diseases. Deposits of amyloid, in the form of hard glistening nodules, give the spleen a characteristic gross appearance, known as "**sago spleen**." A case of **amyloidosis involving the spleen**, diagnosed by FNA, was reported by Pasternack (1974).

Lysosomal storage diseases are characterized by the inability of cytoplasmic **lysosomes** to digest products of lipid, mucopolysaccharide, or glycogen metabolism because of an autosomal recessive inherited **defect of one or more lysosomal**

P.1422

enzymes (known as hydrolases). Various lipid, mucopolysaccharide, or glycogen products, usually derived from membranes of dead cells, are stored in the lysosomes, which often gives the cells a characteristic microscopic configuration. These disorders are classified according to the product stored in the lysosomes. They are usually discovered in infancy or childhood (except for **Gaucher's disease**, which also has an adult form), and result in severe disabilities

and, frequently, early death.

Several of these disorders may involve the spleen. Splenic FNA is rarely, if ever, required for diagnosis, but occasionally a disease presents as a splenomegaly of unknown nature that may be aspirated. The most characteristic cytologic findings are observed in **Gaucher's disease**. **Large macrophages with eosinophilic, finely vacuolated, somewhat striated cytoplasm and peripheral nuclei may be recognized in smears** (Fig. 38-25A,B). The Gaucher cells resemble oncocytes of various origins. Six cases of a not further named "storage disease," presumably Gaucher's, were described by Zeppa et al (1994). A case of Gaucher's disease diagnosed from the splenic aspirate of an infant was reported by Domanski et al (1992).

Hematologic Disorders Affecting the Spleen

Myeloid Metaplasia

Extramedullary hematopoiesis, also known as myeloid metaplasia, is a frequent complication of suppressed or failed hematopoietic function of the bone marrow. It has many possible causes, the most common of which is **myelofibrosis**. The spleen is frequently involved in this process, usually in the form of diffuse splenomegaly. **A tumor-like presentation of myeloid metaplasia of the spleen**, identified by FNA, was reported by Austin et al (2000). The characteristic feature of myeloid metaplasia is a finding of **large, multinucleated megakaryocytes**, accompanied by granulocytic lineage cells and other hematopoietic elements (Fig. 38-26). Identical findings may be observed in **myelolipoma** of the adrenal (see Fig. 40-22).

Leukemias

The spleen is commonly involved in all forms of leukemia, particularly chronic leukemias that may cause large splenomegaly. However, the spleen is particularly affected by **hairy cell leukemia**. In this uncommon form of chronic lymphocytic leukemia that affects B cells, **splenomegaly (sometimes colossal)** may be the dominant clinical feature of the disease (Bouroncle, 1978). **The cells of this form of leukemia display long, slender peripheral**

cytoplasmic projections or “hairs,” accounting for the name of the disease (Fig. 38-27A-C). The enzyme **tartrate-resistant acid phosphatase (TRAP)**, which is present in the cytoplasm of the leukemic cells, distinguishes this from other forms of leukemia. Cases of hairy cell leukemia, diagnosed from splenic aspirates, were reported by Moriarty et al (1993) and Pinto et al (1995). A **monotonous population of large lymphoid cells, some with hair-like projections,** was observed. In the case described by Pinto et al (1995), the diagnosis was confirmed by a **positive TRAP reaction**. If sufficient material is available for flow cytometry, hairy

P.1423

cells are B-lymphocytes that uniquely express CD11c, CD103, and CD25.

Figure 38-26 Myeloid metaplasia of spleen. Three megakaryocytes accompanied by lymphocytes, plasma cells, and immature myeloid cells are seen (cell block of FNA of spleen).

Figure 38-27 Hairy cell leukemia: A. FNA of spleen showing a group of leukemic cells, some with notched nuclei. Cytoplasmic projections are masked by cell clustering and molding. B,C. Characteristic “hairy cells” with peripheral cytoplasmic projections in bone marrow and peripheral blood. (Giemsa stain, oil immersion.)

Malignant Lymphomas

The spleen, being a gigantic lymph node, can be involved in all forms of Hodgkin's and non-Hodgkin's malignant lymphomas (Moriarty et al, 1993; Silverman et al, 1993; Zeppa et al, 1994; Caraway and Fanning, 1997; Austin et al, 2000). Bonifacio et al (2000) advocated the use of flow cytometry on splenic aspirates, guided by ultrasound to increase the accuracy of interpretation of the sample.

Of special interest is the **marginal zone B cell lymphoma that may involve the spleen** as the dominant organ. Matsushima et al (1999) reported on the **diagnostic difficulty** of recognizing this low-grade lymphoma in FNA samples, resulting from the fact that the polymorphous population of lymphocytes in various stages of maturation is suggestive of hyperplastic lymphoid tissue rather than lymphoma. The cytologic presentation of malignant lymphomas in lymph nodes, and the ancillary procedures that are useful in their classification are discussed in Chapter 31.

Hepatosplenic Gammadelta T-Cell Lymphoma

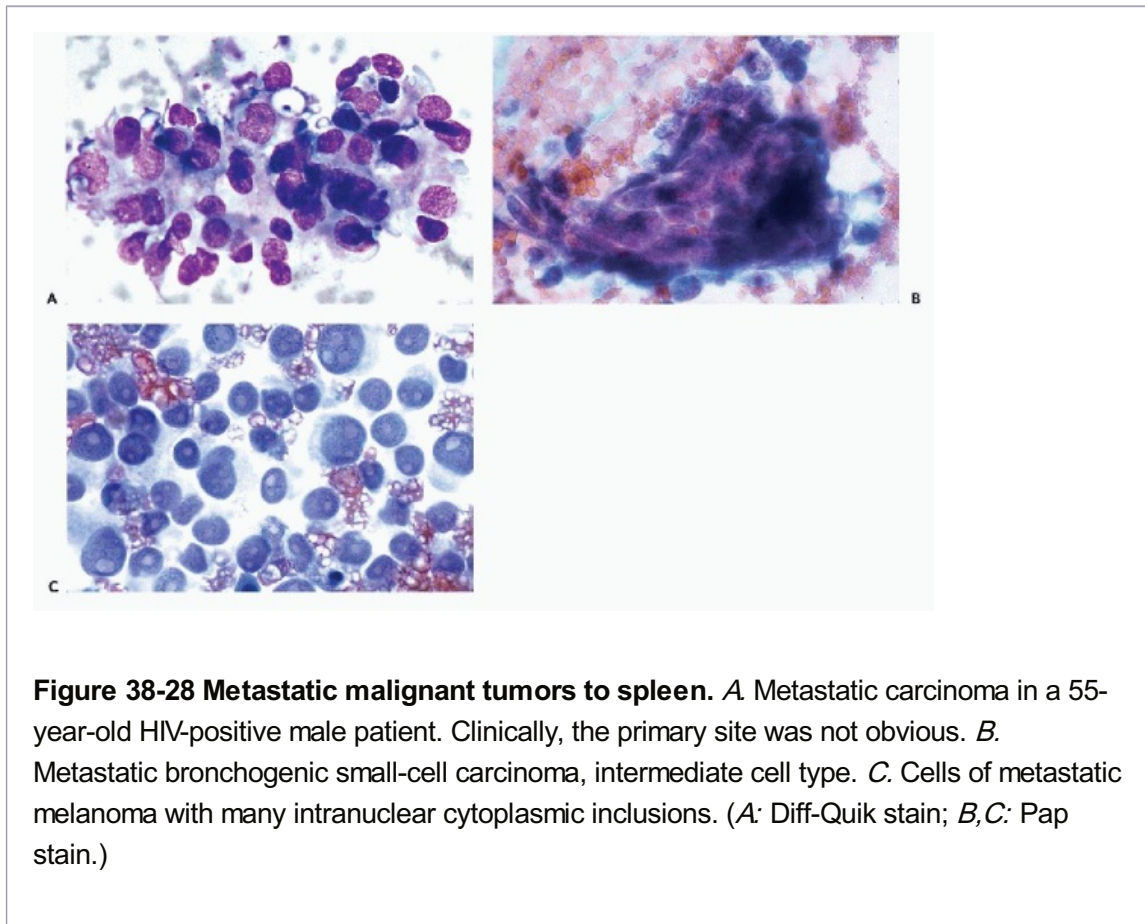

Farcet et al (1990) described a very rare form of malignant T-cell lymphoma that presented as **hepatosplenic disease with hepato- and splenomegaly**, and was characterized histologically by **infiltration of the liver and spleen sinusoids by tumor cells**. The tumor cells expressed a CD3 T-cell receptor with the gamma delta phenotype. A **variant with the alpha beta phenotype** has been described (Suarez et al, 2000). Thrombocytopenia and hemolytic anemia may accompany the disease (Lai et al, 2000). Leukemia may develop in some patients (Steurer et al, 2002). The disease is characterized by aggressive behavior and by short survival of the patients (Weidmann, 2000). To our knowledge, there are no published reports on the cytologic presentation of this disease in FNA spleen samples.

Malignant Histiocytosis

True malignant histiocytosis is a very rare condition **that affects the spleen and the liver**. It is characterized by **erythrophagocytosis by large histiocytic tumor cells, and a rapid clinical course** (Sato et al, 2002). Zeppa et al (1994) illustrated the FNA cytology of this uncommon disease. Large **tumor cells with abundant cytoplasm and large, irregular nuclei** were observed, and the cytologic presentation was **unlike that of any other lymphoma**. The identity of this very rare disorder must be confirmed by markers that indicate the lineage of the malignant macrophages. The markers **CD11c, CD68, macrophage-colony stimulating factor (M-CSF), lysosome, and antitrypsin** were used by Sato et al (2002) to document the identity of the tumor.

Plasmacytoma

A case of **extramedullary plasmacytoma that affected the spleen** and was diagnosed by FNA was reported by Bangerter et al (2000). For description of these tumors, see Chapters 26, 31, and 36.

Vascular Tumors

Angiosarcomas belong to the small group of primary splenic tumors. This disease, which carries a poor prognosis, is characterized by enlarged spleens containing **vascular spaces of various sizes that are lined by large, abnormal endothelial cells** (Enzinger and Weiss, 1995). Although to our knowledge there are no reports of cytologic diagnosis of splenic vascular tumors on FNA, the general cytologic features of angiosarcomas in other locations have been described repeatedly (Mullick et al, 1997; Liu and Layfield, 1999; Boucher et al, 2000). Minimo et al (2002) described the cytologic findings in 24 angiosarcomas of various origins (none of which were in the spleen). In keeping with the observations of other authors, **spindly and epithelioid tumor cells and angioformative structures** were observed in some of the patients, most of whom had a history of vascular neoplasm. These observations may serve as a guide to the obviously difficult cytologic diagnosis of splenic vascular tumors. See also Chapter 35.

Metastatic Cancer

In contrast to the adrenal and the retroperitoneal space, the spleen is not a common site of metastatic cancer. However, sporadic cases of metastatic cancer to the spleen with FNA diagnosis have been reported. Thus, Cristallini et al (1991) described a case of metastatic ovarian carcinoma, and Silverman et al (1993) reported three cases of metastatic carcinoma of testicular, pulmonary, and ovarian origin, respectively. Caraway and Fanning (1997) reported nine cases of metastatic carcinoma from various primary sites, and two metastatic melanomas. In our experience, metastatic cancer to the spleen is most likely to be observed in **immunosuppressed patients, particularly those with AIDS** (Fig. 38-28A). In

immunocompetent patients, metastases are seen more often on the capsule (abdominal carcinomatosis), and rarely within the substance of the spleen (Fig. 38-28B,C).

RESULTS

We do not have sufficient personal experience to establish the statistical accuracy of FNA of the spleen. So far as one can tell from published data, the **diagnostic accuracy** of splenic FNAs for neoplastic processes is somewhat lower than that for other abdominal organs that are routinely aspirated. In a study of 140 patients, Zeppa et al (1994) reported a sensitivity of 86.4% and specificity of 97.5%. Civardi et al (2001) **compared the yield of FNA with core biopsies of the spleen** in 398 procedures and found the two methods to be comparable, with 84.9% accuracy for cytologic sampling and 88.3% for core biopsies. However, **core biopsies were much more efficient for diagnosing malignant lymphoma** (90.9% for core biopsy vs. 68.5% for cytologic sampling). Caraway and Fanning (1997) reported only one false-negative and no false-positive aspirates in 50 patients from a major cancer center, perhaps reflecting the select

P.1425

population. Lishner et al (1996) reported a low yield of diagnoses in 58 patients with a variety of splenic lesions associated with splenomegaly.

It is our belief that in select, well chosen cases in which **FNA can clarify a diagnosis that is not obtainable by other means, and can be performed safely, spleen FNA should retain its place in the diagnostic armamentarium as a valuable and useful procedure.**

The Pancreas

Muhammad B. Zaman

Fine-needle aspiration (FNA) biopsy has made a significant contribution to the preoperative and intraoperative diagnosis of a broad variety of **space-occupying pancreatic abnormalities** that may be benign or malignant. The most common lesions of the pancreas are listed in Table 39-1. Chief among the malignant lesions are **ductal adenocarcinomas**, which are largely incurable and often rapidly fatal (Gudjonsson, 1987; Warshaw and Swanson 1988; Henne-Bruns et al, 1998). It is not clear at this time whether cytologic techniques will contribute to an improved salvage rate for these patients. However, because of its safety and reliability, **FNA of the pancreas has greatly reduced the need for exploratory laparotomies**, which are not without the risk of operative morbidity and mortality (Ferrucci et al, 1979). Substantial **savings in health care expenditures** more than justify the use of the needle aspiration technique (Soudah et al, 1989; Alvarez et al, 1993; Chang et al, 1997). The practicing cytopathologist who interprets the FNA smears of a pancreatic tumor may be rewarded by the diagnosis of a benign condition or tumors that may be curable by surgical resection. Fortunately, these relatively rare tumors, which constitute approximately 10% of pancreatic neoplasms (an estimated 3,000 cases annually in the United States) are recognizable because of their unique cytomorphology.

INDICATIONS AND DIAGNOSTIC TECHNIQUES

The principal reason for investigating the pancreas is to differentiate between inflammatory and neoplastic space-occupying lesions, and, if the lesion is neoplastic, to determine whether it is amenable to effective treatment. The initial step in investigating a patient with a pancreatic lesion is to determine the **serum amylase and lipase levels**. These levels are usually markedly elevated in acute pancreatitis, but are only slightly elevated in chronic pancreatitis or in the presence of a pancreatic carcinoma. If a satisfactory diagnosis has not been achieved on the basis of clinical presentation and biochemistry, **imaging studies** of the pancreas are usually the next step in the evaluation of pancreatic disease.

The investigation of pancreatic lesions is based on a variety of **imaging techniques**, such as computed tomography (CT), ultrasound (US), endoscopic US (EUS), endoscopic

P.1429

retrograde pancreatography, and angiography, and the use of radioactive tracer substances (e.g., 75 selenomethionine scans). **If a space-occupying lesion is observed or suspected, the identity of the lesion must be further established. Cytologic techniques are currently the diagnostic methods of choice.**

TABLE 39-1 COMMON LESIONS OF THE PANCREAS

Inflammatory Lesions	Neoplastic Lesions
Pancreatitis	Cystadenoma
Acute	Pancreatic carcinoma
Subacute and chronic	Duct cell origin
Pseudocysts	Acinar origin
Cysts	Cystadenocarcinoma (mucinous-cystic neoplasm)
	Solid-papillary neoplasm
	Islet cell tumor (pancreatic endocrine tumor)
	Metastases to pancreas

Methods of Securing Pancreatic Samples

There are four methods available to secure cytologic samples from the pancreas:

- Duodenal lavage
- Endoscopic cytologic sampling via the common bile duct, using US or retrograde pancreatography
- Cytology of pancreatic juice
- Transcutaneous, intraoperative, or EUS-guided FNA

The first two methods are described and discussed in Chapter 24, and only the cytology of FNA and pancreatic juice are discussed in this chapter.

Collection of Pancreatic Juice

In several studies, Japanese researchers investigated the diagnostic value of pancreatic juice, which is collected with or without papillotomy of the opening of the pancreatic ducts into the common bile duct. Their results were encouraging. Cytologic studies of the juice allowed for a **better classification** of mucin-producing tumors of the pancreas (Uehara et al, 1994), and for the occasional discovery of noninvasive **intraductal carcinoma** (Shimizu et al, 1999).

Techniques of Pancreatic Aspiration

The principal indication for FNA is the identification of a **space-occupying solid or cystic lesion** of the pancreas. In the latter situation, aspiration may serve as both a diagnostic and a therapeutic procedure. **FNA is more likely to provide an accurate diagnosis** compared to intraoperative core needle or wedge biopsy of the pancreas (Moossa et al, 1982; Saez et al, 1995).

There are three principal approaches to performing diagnostic FNA of the pancreas:

- **Percutaneous transabdominal aspiration** under US or CT guidance. The success of this method depends on the skill of the operator in guiding the needle to the target area and obtaining an adequate sample. The **adequacy of the sampling procedure** may be determined at the bedside by rapid microscopic examination of aliquots of the samples by trained personnel. In our experience, adequate samples can be obtained from nearly all pancreatic cancers; however, in some cases the aspiration must be repeated.
- **EUS-guided FNA.** This is a newer approach that can be utilized to sample small pancreatic carcinomas (Chang et al, 1997; Jhala et al, 2003). The procedure is tedious and requires operator experience and collaboration between the cytopathologist and endoscopist. It is now the standard of practice in large medical centers.
- **Direct visualization or palpation of the pancreas** at the time of a **laparotomy**. This was the initial method used for cytologic investigations of the pancreas before reliable imaging techniques became available (Arnesjo et al, 1972). The advantage of this method is that it can precisely locate the pancreatic lesion with excellent accuracy and very few complications (Hastrup et al, 1977; Stormby, 1979; Alpern and Dekker, 1985; Soudah et al, 1989; Edoute et al, 1991; Blandamura et al, 1995; Saez et al, 1995). The samples are not contaminated by cellular material from serosal, gastric, or intestinal tissues.

Comparison of Intraoperative Aspiration With Tissue Biopsies

Intraoperative aspirations are **probably more efficient and accurate** than **intraoperative wedge or needle core tissue biopsies** with intraoperative consultation with frozen sections, which is occasionally done during exploratory laparotomies for pancreatic tumors, particularly when resection of the head of the pancreas is contemplated (Whipple procedure) (Saez et al, 1995; Robins et al, 1995). However, even the small, direct tissue biopsies are not free of the risk of significant morbidity and mortality, and they are not always easy to interpret (Ferucci et al, 1979; Beazley, 1981). The fear of causing acute pancreatitis and peritonitis resulting from the leakage of enzymes, and the difficulty in differentiating chronic pancreatitis from pancreatic carcinoma by gross examination at surgery often results in the acquisition of inadequate tissue samples. Crushing of the small biopsy sample may also create problems in interpretation.

Complications

There are rare reported complications of intraoperative FNA under visual guidance (Simms, 1982), and remarkably few complications of percutaneous FNA, even though the needle passes through a number of viscera, such as the large bowel, before reaching the pancreas. Apparently, the needle puncture sites are rapidly sealed. The complications that

P.1430

have been reported include cases of **acute pancreatitis**, **needle tract seeding** of pancreatic carcinoma, and **pancreatic fistula** (McLoughlin et al, 1978; Ferrucci et al, 1979; Simms et al, 1982; Rashleigh-Belcher et al, 1986; Bergenfeldt et al, 1988; Fornari et al, 1989; Rosenbaum and Frost, 1990). A case of **bile peritonitis** was encountered in a patient with carcinoma of the head of pancreas and a distended Courvoisier gall bladder. The perforation was immediately apparent because of the presence of bile in the syringe; however, the patient recovered after laparotomy and treatment with antibiotics (Koss et al, 1992). The frequency of complications from FNA is much lower than that associated with incisional pancreatic biopsies.

ANATOMY, HISTOLOGY, AND CYTOLOGY OF THE NORMAL PANCREAS

Anatomy

The pancreas is a catfish-shaped, composite exocrine-endocrine gland that is located transversely in the upper abdomen behind the peritoneum. The gland itself weighs approximately 100 g, measures about $25 \times 9 \times 4$ cm, and is posterior to the body and antrum of the stomach and the transverse colon (see Fig. 24-1). The pancreas is arbitrarily divided into three parts: **the head, body, and tail**. The head is nestled in the duodenal C loop behind the liver, and the tail extends to the hilus of the spleen (see Chap. 24). The left kidney is immediately posterior to the tail. With so many structures in close proximity, it is clear that when one attempts to reach a pancreatic lesion through the anterior abdominal wall, the needle may sample mesothelial cells from the peritoneum and normal cells from any of the above mentioned organs. **Ectopic pancreases** may be observed and sometimes may cause diagnostic problems (Sams et al, 1990).

Figure 39-1 Histology of normal pancreas. *A.* Exocrine pancreas. Pancreatic lobules composed of acini separated from each other by septa of connective tissue form the lobule. The secretory duct is lined by columnar mucus-forming cells. *B.* Islet of Langerhans and acinar cells. The islets are composed of small polyhedral cells with transparent cytoplasm that are arranged in nests separated by capillaries. By contrast, the larger acinar cells with purple cytoplasm are shown in the middle of the field.

The bulk of the pancreas is formed by the **exocrine component**, namely the acini, the ducts, and the corresponding blood vessels. The **endocrine component**, which is comprised of more than a million **islets of Langerhans** with an aggregate weight of about 1 g, constitutes about 2% of the pancreatic mass. The remaining approximately 10% of the pancreas is formed by the extracellular matrix (Gorelick and Jamieson, 1981).

Histology

The histology of the **exocrine pancreas** is similar to that of the salivary glands. The exocrine pancreas is composed of morphologic units called **lobules**, which are made up of numerous **spheroidal acini** (Fig. 39-1A). The lobules are separated by a thin fibroconnective and vascular stroma. The acini produce **digestive enzymes**, such as trypsinogen, chymotrypsin, lipase, and elastase. These enzymes drain into the duodenum by a complex **duct system**. The smallest intralobular ducts, which are lined by a flattened epithelium, continue into the interlobular ducts with cuboidal epithelium, and then into the main excretory ducts, which are lined by columnar cells with interspersed goblet cells (Fig. 39-1A). The ductal system is

embryologically related to the extrahepatic biliary tract, and is morphologically similar to the bile duct and gall bladder epithelium (see Chap. 24).

The pancreatic acini are lined by pyramid-shaped cells surrounding a central small lumen. They have basally placed round nuclei, and the pink to purple cytoplasm contains variable numbers of acidophilic zymogen granules (Fig. 39-1B).

The richly vascularized **islets of Langerhans** are dispersed throughout the whole organ; however, most are located in the tail of the pancreas. The islets are composed of small polyhedral cells arranged in nests and separated by capillaries. The cytoplasm of the islet cells is transparent; therefore, they are seen in histologic sections as a collection

P.1431

of small clear cells, approximately five times the size of an acinus (Fig. 39-1B). The islets do not maintain communication with the acinar or ductal system, and they secrete their products directly into the bloodstream. Depending on the hormones produced, the islet cells may be classified as **α cells** (which produce glucagon), **β cells** (insulin), **δ cells** (somatostatin), **G₁ cells** (gastrin), and **PP cells** (polypeptide). These cell types are identified on the basis of immunohistochemistry or electron microscopy (Mukai et al, 1982). Regardless of type of cell involved, tumors derived from islet cells, known as pancreatic endocrine neoplasms, are morphologically similar to each other.

Cytology

Normal pancreas is never deliberately aspirated, and information regarding its cytologic make-up is obtained mainly from aspirates of very small lesions that have missed the target. Although the normal exocrine pancreas is composed primarily of acini, the dominant cells in FNA smears are **ductal epithelial cells**. Normal acinar cells and islet cells are rarely seen (see below). The percutaneous transabdominal pancreatic aspirates may also contain mesothelial cells, epithelial cells of gastric or intestinal origin, occasionally hepatocytes, and, very rarely, ganglion cells (Fig. 39-2A-D).

Figure 39-2 Cytology of normal pancreas. A. Ductal cells arranged in a large monolayer folded at the edges. B. Higher magnification shows uniform small cuboidal ductal cells in a

honeycomb arrangement. Single cells, as well as mucus vacuoles, are generally absent. *C,D. Pancreatic acini or cells forming “rosettes.”* The nuclei are aligned at the periphery with narrow central lumen. The cytoplasm may be clear (*C*) or purple and granular (*D*).

Epithelial Duct Cells

Benign ductal cells of the pancreas appear as **sheets of uniform cuboidal cells forming monolayers of various sizes** with centrally placed small nuclei (see Fig. 39-1C). At the edge of clusters derived from large ducts, the cells may be **columnar** in configuration, parallel to each other, with basally placed nuclei. The cytoplasmic borders are well demarcated and the cytoplasm is transparent in fixed smears stained with Papanicolaou stain, accounting for the **honeycomb pattern** of the flat clusters (Fig. 39-2B). Cytoplasmic vacuoles or goblet cells are very rarely seen. The **nuclei** are round or slightly ovoid, and equally spaced, and there are no nuclear contour abnormalities. The **chromatin** is finely granular and uniformly distributed. Tiny **nucleoli** may be visible.

Occasionally, large areas of the ductal epithelium are aspirated (Fig. 39-2A). The smear may show very large flat sheets of benign glandular cells that may fold at the edges. Occasionally, the ductal cells form **thick, multilayered sheets** with crowding of nuclei. Such clusters may be a cause for concern because this may represent a well-differentiated ductal adenocarcinoma.

Examination of the edges of such thick clusters usually allows for a close examination of the nuclei that fail to show the nucleolar abnormalities characteristic

P.1432

of cancer. The absence of single cancer cells is another reason to regard such clusters as benign.

Acinar Cells

The acinar cells usually form **small, tightly knit clusters, often arranged in spherical, three-dimensional structures**. Higher magnification reveals the **pyramidal shape** of cells arranged around a **central narrow lumen**, resembling **rosettes**, with the nuclei aligned at the periphery of the cells (Fig. 39-2C,D). The **cytoplasm** is relatively abundant, and in air-dried or well-fixed cells it may show prominent **coarse cytoplasmic granularity** imparted by the **zymogen granules**, which are precursors of digestive enzymes. In most cases, however, the granules are lost, and the cytoplasm of the acinar cells appears clear or vacuolated (Hastrup, 1977). The **nuclei** are uniform and small and round, with a smooth membrane, and are located away from the acinar lumen. The **chromatin** is granular and evenly distributed, and the nucleoli are inconspicuous.

Islet Cells

In general, the **islet cells cannot be recognized in FNA smears** without the use of immunohistochemical markers for endocrine function. In a fortuitous case of pancreatic FNA performed in a young male patient with sclerosing cholangitis and total atrophy of the exocrine pancreas, the aspirated **islet cells formed loose, approximately spherical or oval aggregates of cells with eosinophilic cytoplasm** (Fig. 39-3A). The cell borders were indistinct, and in this material cytoplasmic granules were not visible. The regular round **nuclei** with minimal pleomorphism were similar in size to the acinar cell nuclei. The nuclear **chromatin**

may show an endocrine “**salt and pepper**” granularity, with a visible nucleolus. In this particular case, the identity of the cells was confirmed at autopsy (Fig. 39-3B). It must be reemphasized that this presentation of islet cells is exceptional and is not likely to be duplicated in practice.

Other Benign Cells

Large sheets of benign glandular cells may be aspirated from **gastric or intestinal** (mainly colonic) mucosa. However, **benign gastric mucosal cells** are identical to pancreatic ductal epithelium (Fig. 39-4A). The origin of the sample can be identified if **parietal gastric cells**, which have a finely granular and intensely eosinophilic cytoplasm, are present. The presence of **goblet cells identifies intestinal epithelium** (Fig. 39-4B).

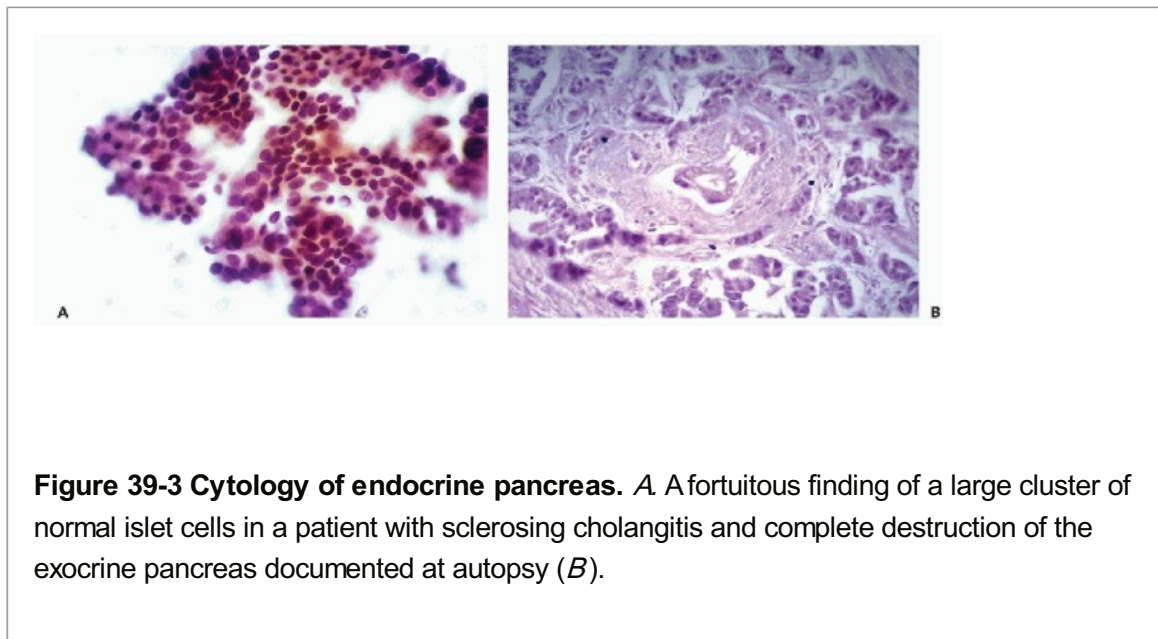

Figure 39-3 Cytology of endocrine pancreas. *A.* A fortuitous finding of a large cluster of normal islet cells in a patient with sclerosing cholangitis and complete destruction of the exocrine pancreas documented at autopsy (*B*).

The **mesothelial cells** of peritoneal origin typically occur in **monolayer sheets**, in which the cells are separated from each other by wide spaces or **windows**. These cells have notoriously **large, readily visible nucleoli**, and therefore may be confused with cancer cells (see Fig. 38-1D; for further discussion and illustrations of these cells, see Chap. 25). **Large hepatocytes**, occurring singly or in small sheets, may be present in smears if on its way to the pancreas the needle passes through the left liver lobe (see Fig. 39-4C). Their morphology is described in Chapter 38. Capillary vessels, connective tissue cells, and sometimes striated muscle and fat cells may also occur in pancreatic FNA smears. Exceptionally, when the needle penetrates beyond the pancreas and reaches sympathetic ganglia, **ganglion cells** may be observed (Fig. 39-4D).

INFLAMMATORY LESIONS: PANCREATITIS

The term **pancreatitis** is used to describe **injury to the exocrine component of the pancreas**, primarily the acini, with resulting **release of digestive enzymes**, lipase, elastase, and proteases, leading to the **autodigestion** of the pancreas and the surrounding tissues. This results in a hemorrhagic necrosis and inflammation of the affected tissues, mainly **fat necrosis**. The combination of the necrotic fat with calcium salts may result in **calcific soap formation**, which is readily visible as white granules within the peripancreatic fat.

The known **predisposing factors** are gallstones with associated obstruction and infection,

alcoholism, trauma (including abdominal surgery), and sometimes malignant tumors of the pancreas. Less often, drugs and gastric ulcers

P.1433

may also be associated with pancreatitis (Marshall, 1993). The pathogenesis of pancreatitis is poorly understood. **The formation of pseudocysts** may be a consequence of pancreatitis (see below).

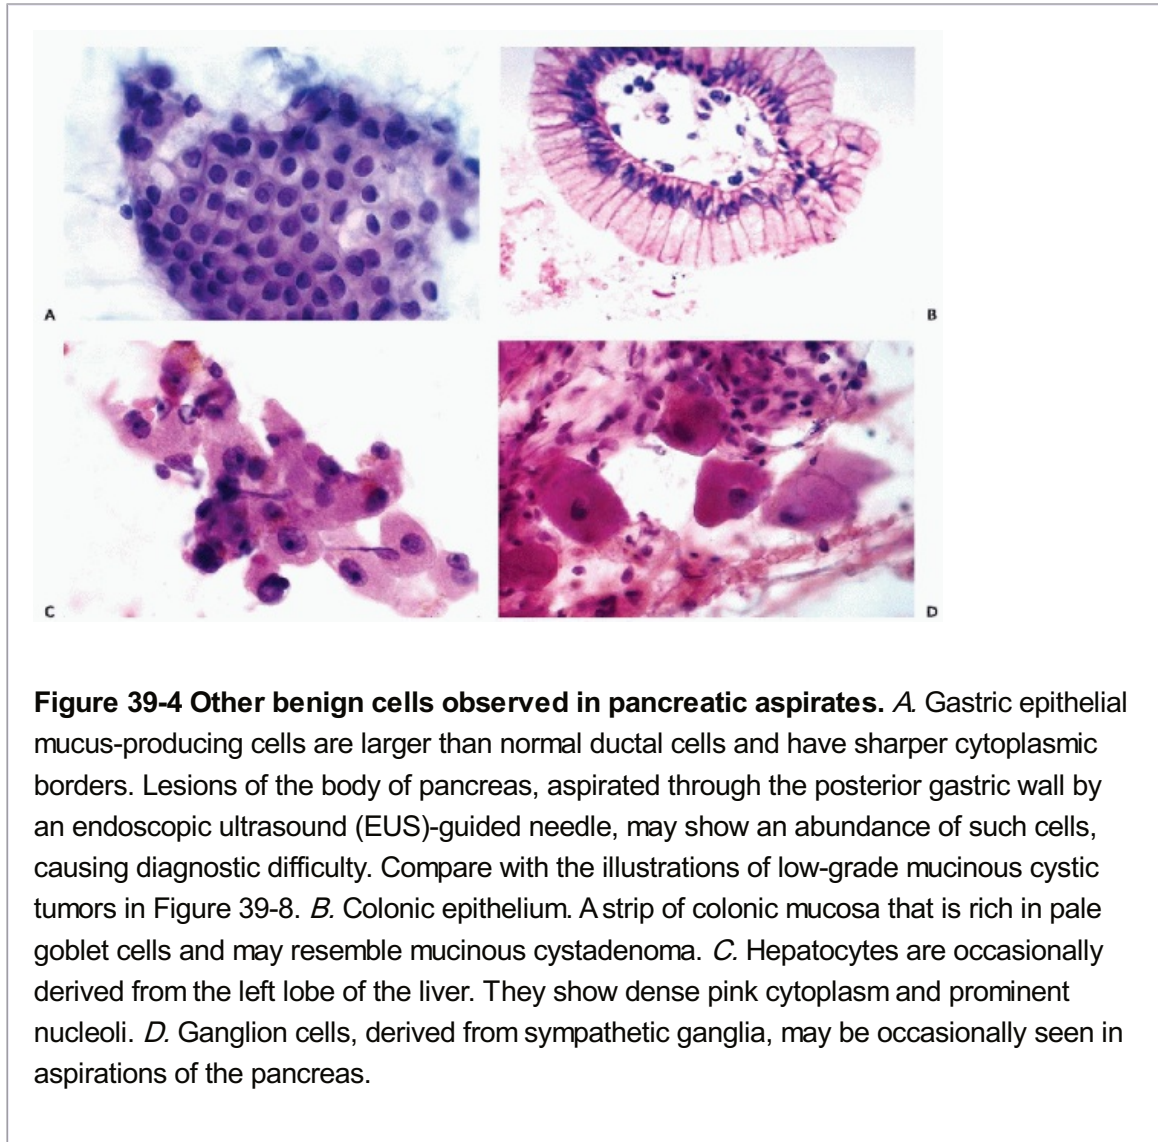

Figure 39-4 Other benign cells observed in pancreatic aspirates. *A.* Gastric epithelial mucus-producing cells are larger than normal ductal cells and have sharper cytoplasmic borders. Lesions of the body of pancreas, aspirated through the posterior gastric wall by an endoscopic ultrasound (EUS)-guided needle, may show an abundance of such cells, causing diagnostic difficulty. Compare with the illustrations of low-grade mucinous cystic tumors in Figure 39-8. *B.* Colonic epithelium. A strip of colonic mucosa that is rich in pale goblet cells and may resemble mucinous cystadenoma. *C.* Hepatocytes are occasionally derived from the left lobe of the liver. They show dense pink cytoplasm and prominent nucleoli. *D.* Ganglion cells, derived from sympathetic ganglia, may be occasionally seen in aspirations of the pancreas.

Acute Pancreatitis

Acute pancreatitis may range from a mild and self-limited disorder to a severe, debilitating, even fatal disease. Classically, there is an abrupt onset of **severe abdominal pain** radiating to the back, with a marked **elevation of serum amylase and lipase levels**. The episode is often precipitated by excessive alcohol or food consumption. The diagnosis is usually clinically obvious and can be confirmed by biochemical analysis of the serum or, by contrast, **enhanced dynamic pancreatography**, a refined CT technique that can detect pancreatic necrosis and its extent. This imaging procedure correlates with the severity of the pancreatitis and other complications (Marshall, 1993). Therefore, percutaneous FNA biopsy is usually not needed and is seldom performed.

The limited information available regarding the **cytology** of acute pancreatitis comes from **intraoperative needle aspirations** obtained during exploratory laparotomies. Arnejo et al

(1972), Hastrup et al (1978), and Frias-Hidvegi (1988) reported the presence of inflammatory cells, macrophages, lipophages, and elements of normal pancreas (mainly ductal cells). The presence of **calcific debris** from areas of fat necrosis has also been reported.

Subacute and Chronic Pancreatitis

Subacute or chronic pancreatitis is usually the sequela of an acute pancreatitis, but it may also occur as a primary disorder. The patients have **chronic recurrent abdominal pain**. The levels of serum amylase and lipase may or may not be elevated. Late in the course of the disease, **pancreatic insufficiency** in the form of steatorrhea, weight loss, and diabetes mellitus may develop. Chronic pancreatitis **may also cause bile duct obstruction and jaundice**; therefore, it may be mistaken clinically for a pancreatic carcinoma.

P.1434

Histology

In tissue sections, chronic pancreatitis is characterized by variable degrees of **fibrosis, acinar atrophy, and ductal hyperplasia**. As a result of atrophy of the exocrine pancreas, the **islets of Langerhans** are readily visible and appear larger than normal. The **stroma** shows an infiltrate composed of lymphocytes and plasma cells. The **epithelium** of the dilated and distorted ducts may show **hyperplasia with some atypia**, and, rarely, **squamous metaplasia** in the smaller ducts. The duct lumens may be filled with protein plugs. In the end stage of the disease, the ducts may be **distorted by diffuse fibrosis** and may show mucinous metaplasia, thus **mimicking a well-differentiated adenocarcinoma of the scirrhous type** (Fig. 39-5A). **Fat necrosis** with calcium deposits is commonly observed at the periphery of the pancreatic tissue. At laparotomy, the pancreas may be rock-hard on palpation, grossly mimicking infiltrating carcinoma. It **can be a formidable problem to correctly interpret needle core biopsies by frozen sections**. Cytologic studies may help in difficult situations.

Cytology

The FNA smears of subacute and chronic pancreatitis vary in cellularity and cell composition, but, contrary to pancreatic cancer, are **usually scanty**. On screening magnification, the smears typically reveal a **polymorphous** picture of variably sized and configured clusters of **ductal cells, occasional acinar cells, macrophages** and other **inflammatory cells, connective tissue fragments, granulation tissue, mucus, calcification, and debris** (Fig. 39-5B,C). Not all of these components are seen in a given case. The number and type of inflammatory cells present depend on the stage of the disease: In **subacute pancreatitis**, neutrophils and macrophages predominate. In **chronic pancreatitis**, lymphocytes, macrophages, and plasma cells predominate. In **chronic fibrosing pancreatitis**, the FNA smears may have a relatively clean background.

Figure 39-5 Chronic pancreatitis. *A.* Histology of chronic fibrosing pancreatitis. The ducts, distorted and separated from each other by dense stroma containing scattered lymphocytes, mimic an adenocarcinoma (same case as *D*). *B.* The hyperplastic ductal cells are crowded but retain polarity. Background inflammatory cells are predominantly lymphocytes. *C.* A connective tissue fragment represents fibrosis. *D.* A cluster of ductal cells. Some cells show distended clear cytoplasm, consistent with mucinous metaplasia, but there is no nuclear contour abnormality.

Problems with interpreting pancreatic material in pancreatitis are related to the presence of **hyperplastic and atypical ductal cells, which may occur singly or form disorderly clusters** (Fig. 39-5D). In some (fortunately very uncommon) cases, **nuclear atypia** in the form of **nuclear enlargement and clearly visible but not very large nucleoli** makes it **extremely difficult to differentiate chronic pancreatitis from well-differentiated adenocarcinoma**. The presence of an **inflammatory infiltrate in the background of the smear** should strongly suggest the use of **caution** before interpreting such smears as malignant. The

P.1435

important factors in the differential diagnosis of inflammatory atypia of ductal cells versus well-differentiated ductal carcinoma are discussed below in reference to carcinoma, and are summarized in Table 39-3 (see below). An additional confounding factor is that **ductal carcinoma and chronic fibrosing pancreatitis may coexist** and may account for at least some of the false-negative diagnoses on FNA of this organ.

NONNEOPLASTIC CYSTIC LESIONS

Pancreatic cysts represent a broad variety of lesions that may be acquired or congenital, benign or malignant. Rarely, some of the **otherwise solid tumors, such as pancreatic duct carcinoma or endocrine tumor, may also be wholly or partially cystic**. In such cases, **the aspiration of the cystic fluid should be supplemented by an aspiration of the cyst wall to reach the correct diagnosis**. Several major recent surveys of FNA cytology of various cysts have documented the diversity of the targets and the problems encountered in identifying them (Koss et al, 1992; Laucirica et al, 1992; Centano et al, 1997).

Acquired Cysts

Pancreatic Pseudocysts

The most common type of acquired nonneoplastic cysts is the **pancreatic pseudocyst**, which follows the destruction and necrosis of pancreatic tissue secondary to pancreatitis. Patients usually present with jaundice, pain, weight loss, nausea, and vomiting. Pseudocysts are usually **solitary and unilocular**, and while their cystic nature may be determined by CT or US, it is not possible to exclude a cystic neoplasm based on imaging alone. Therefore, the nature of the cyst should be determined by cytologic examination of the cyst contents.

Histology

The thick cyst wall consists of **reactive fibrous tissue without epithelial lining** (hence the name *pseudocyst*). Initially, most pseudocysts are small, but continued pancreatic secretion and destruction of tissues may lead to very large symptomatic and even palpable cystic masses containing several hundred cubic centimeters of fluid.

Cytology

Aspiration of fluid from a pseudocyst is often of **diagnostic and therapeutic value**. After the fluid is aspirated, the cyst may collapse and the patient will experience immediate symptomatic relief. Often there is no reaccumulation of the fluid.

The **cyst fluid** may appear clear, straw-colored, brown, turbid, or frankly hemorrhagic. The **sediment** is sometimes **acellular** but most often contains large numbers of **macrophages** and some **lymphocytes in a background of necrotic debris** (Fig. 39-6A). Less often, there are **multinucleated macrophages** containing ingested hemosiderin and debris, and a very few **atypical spindly fibroblasts with enlarged nuclei and prominent nucleoli** originating in the capsule of the pseudocyst. The latter can be mistaken for a spindle cell malignant tumor. The small number of such cells, and the typical cystic background of the smear should prevent such errors. **Epithelial cells are absent. If epithelial cells are present, the lesion is not likely to be a pseudocyst.** A portion of the cyst fluid should always be submitted for **analysis of amylase content**, that is high in pseudocyst, and **carcinoembryonic antigen (CEA) level**, which is **high in neoplastic cysts but low in pseudocysts** (Pinto and Meriano, 1991; Lewandrowski et al, 1993; Centeno et al, 1997).

Lymphoepithelial Cysts

These are uncommon cysts that are similar to branchial cleft cysts in the neck (see Chapter 30) and are often lined by **squamous epithelium with lymphocytic deposits in the wall** containing pasty, whitish material. There are a few case reports describing the cytologic findings (Centeno et al, 1999; Liu et al, 1999; Mandavilli et al, 1999). The presence of **squamous cells, squamous and amorphous debris, and cholesterol crystals** has been described as characteristic of the entity (Fig. 39-6B). Centeno et al (1999) reported **elevated levels of CEA, CA 125, and amylase** in the viscous fluid aspirated from one such cyst.

Congenital Pancreatic Cysts

Congenital pancreatic cysts are rare, **true cysts lined by pancreatic ductal epithelium**. They can be **solitary** (thought to result from abnormal development of a duct) or **multiple** (associated with inherited **polycystic diseases**). The capsule is thin and lined by a single

layer of **cuboidal, rarely columnar, or flat epithelial cells**, some of which show evidence of mucus formation (Fig. 39-6D).

The **aspirated fluid** is usually clear and mucoid, and the smears are sparsely cellular. Careful screening usually reveals a few benign cuboidal or columnar epithelial cells from the lining of the cyst (Fig. 39-6C). If such cells are numerous, the possibility of a mucinous cystic tumor cannot be ruled out (see below).

BENIGN AND MALIGNANT NEOPLASTIC CYSTIC LESIONS

Serous Cystadenoma

A serous cystadenoma is a benign epithelial neoplasm composed of **numerous small cysts lined by uniform glycogen-rich cuboidal cells**, sometimes disposed around a **central stellate scar**. The lesions are also known as **microcystic adenomas or glycogen-rich adenomas** (Compagno and Oertel, 1978a; Alpert et al, 1988). They constitute 1% to 2% of the exocrine pancreatic tumors, and are of unknown

P.1436

etiology and pathogenesis. These tumors occur **predominantly in elderly women** (mean age of 66 years), but they may also occur in men, and are usually, but not always, located in the **body and tail of the pancreas** (Compagno and Oertel, 1978; Albores-Saavedra, 1990). A **macrocytic variant** of this tumor was described by Lewandrowski et al (1992). The tumor can be asymptomatic and incidently found during abdominal examination for unrelated disease, or it may cause nonspecific symptoms related to its bulk, such as abdominal pain, nausea, and vomiting. Grossly, these tumors are **well-circumscribed and large**, with an average diameter of 10 cm. The cut surface has a characteristic **sponge-like appearance** due to the presence of numerous cysts of variable size (hence the name *microcystic adenoma*).

Figure 39-6 Nonneoplastic cysts of the pancreas. *A.* Pancreatic pseudocyst. The sediment contains foamy macrophages and lymphocytes, but there are no epithelial cells. The background is clean but may contain necrotic debris. *B.* Lymphoepithelial cyst of the pancreas. The presence of squamous cells is highly suggestive of this disorder. Lymphocytes and macrophages are also present. A dermoid cyst cannot be excluded. *C.* A

mucinous (congenital) cyst. The processing of 9 cc of clear mucus aspirated from a pancreatic cyst yielded only a few small groups of benign columnar mucinous cells. *D*. Histology of a benign mucinous cyst. The single layer of lining mucus cells is separated from the thick, fibrous capsule. This cyst was an incidental finding in a pancreas removed for a carcinoma.

Histology

The cysts are lined by a single layer of **uniform cuboidal or flattened epithelial cells with clear glycogen-containing cytoplasm**, and may show **intracystic papillation**, usually without a fibrovascular core (Fig. 39-7D). The central **stellate scar** is formed by fibrous, hyalinized tissue with a few clusters of tiny cysts.

Cytology

The aspirate yields small amounts of clear, watery fluid. The cellularity of the smear is variable and may be abundant in a vigorous aspirate (Fig. 39-7A-C). At low magnification, the smear gives the impression of **numerous, tightly cohesive normal acini**, which actually represent the microcysts and small intracystic papillae. At high magnification, the **small papillary groups are made up of uniform small cells with transparent, well-delineated cytoplasm**. Some **flat sheets of epithelial cells** of variable sizes may be encountered; however, a perfect honeycomb pattern, as found in sheets of benign ductal cells, is not seen. **Periodic acid-Schiff (PAS) stain is positive**. The **nuclei** are spherical and show very little, if any, pleomorphism or atypia. Similar findings, with slight variations in cytologic presentation, were reported by Hittmair et al (1991) and Nguyen and Vogelsang (1993).

A malignant counterpart—serous cystadenocarcinoma—has been reported (George et al, 1989). We have

P.1437

no first-hand experience with such a lesion in aspiration smears.

Figure 39-7 Neoplastic cysts of the pancreas. *A,B*. Serous cystadenoma. In the

aspiration smear, the monotonous cuboidal cells with well-defined cytoplasm form either flat clusters or acini-like structures, depending on the lining of the locule (flat or papillary). The background is clean, with no mucus. *C.* Acinus in Diff-Quik stain. On immediate assessment, an acinar cell carcinoma and endocrine tumors must be considered in the differential diagnosis. *D.* Histology of serous cystadenoma. Portions of two microcysts are lined by uniform cuboidal cells, forming papillary projections.

Mucinous Cystic Tumors

Clinical Data and Histology

Mucinous cystic tumors are uncommon pancreatic neoplasms, representing approximately 2% to 5% of all exocrine pancreatic tumors (Thompson et al, 1999). More than 500 cases of this tumor have been reported (Compagno and Oertel, 1978b; Zamboni et al, 1999). The tumors are composed of **cysts lined by columnar, mucin-producing epithelium** supported by **ovarian-type stroma**. They are **subclassified as adenoma, borderline malignant, or noninvasive or invasive carcinoma** according to the **level of abnormality of the epithelium**, which may form single or multiple layers or papillary projections (Fig. 39-8D). There are many similarities between this pancreatic tumor and its ovarian equivalent (see Chap. 15). Mucinous cystic tumors of pancreas occur **almost exclusively in middle-aged women** (Zamboni, 1999) in the body or tail of the pancreas. The smaller tumors may be an incidental finding, whereas larger tumors may produce nonspecific symptoms of pressure and **diabetes mellitus**. Malignant mucinous cystic tumors are often slow-growing and have a much better prognosis than pancreatic ductal carcinoma (Warshaw, 1990). No deaths from cancer have been observed in patients classified as benign or borderline malignant (Warshaw et al, 2003). Thus, the recognition and accurate classification of the cystic tumors is of great clinical value.

Cytology

The characteristic feature of fine-needle aspirates of mucinous cystic tumors is the presence of a **grossly obvious clear mucoid material that forms the background of the smears**.

Mucus is much easier to recognize as a **stringy, purple substance in air-dried smears**, stained with hematologic stains, than as a faintly pink background in fixed smears processed with Papanicolaou's stain. If the cyst is large, the cell content of the smear may be very low.

Smaller cysts yield numerous epithelial cells. In the benign and borderline mucinous cystic tumors, the cells form flat sheets with a "honeycomb" pattern **closely resembling normal duct epithelium** in a background of mucus (Fig. 38-8A). In other cases, sheets of goblet cells, floating in mucin, may be observed (Fig. 39-8B). As a point of differential diagnosis, occasional goblet cells may occur in aspirates from chronic pancreatitis, but they are never numerous and the smears do not have a mucinous background. In borderline tumors, small clusters and single cells with visible nucleoli are common (Fig. 39-8C). Furthermore,

P.1438

careful scrutiny of smears from high-grade mucinous cystic tumors reveals papillary or three-dimensional groups with obvious nuclear atypia. Frankly malignant tumors of this category are classified as mucinous adenocarcinoma (see Fig. 39-16A,B) and are cytologically identical to colloid (mucinous noncystic carcinoma; see below). A positive mucin stain excludes serous cystadenoma (Table 39-2). Rubin et al (1994) reported that benign and malignant mucinous cystic neoplasms can be differentiated by the level of the **tumor marker CA 15.3 in the cyst**

fluid.

Figure 39-8 Neoplastic cysts of the pancreas. *A.* Mucinous cystadenoma. A large sheet of epithelial cells in a honeycomb-like arrangement is shown on a background of thick, clear mucus. No nuclear abnormalities or nucleoli are seen. Compare with normal pancreatic ductal cells and gastric mucus cells (Figs. 39-2B and 39-4A). *B.* Dispersed goblet cells, elongated by the smearing process, in a background of mucus. *C.* Borderline intraductal papillary mucinous tumor. The smear shows numerous mucus-producing cells. An occasional nucleolus can be noted. *D.* Histology of the tumor shown in *C.* The neoplastic ductal cells form slender papillary projections confined to the duct. Elsewhere the epithelium was atypical, and the tumor was classified as “borderline.”

TABLE 39-2 DIFFERENTIAL DIAGNOSIS OF FLUIDS ASPIRATED FROM PANCREATIC CYSTS

	Pseudocyst	Serous Cystadenoma	Mucinous Cystic Tumour
Gross Appearance	Usually brown turbid to bloody	Water clear	Clear mucinous (sticky)
Cellularity	Sparse	Moderate to high	Sparse to moderate in mucus background
Types of cells	Macrophages and debris; no epithelial cells	Small group in tight cohesion or honeycomb	Honeycomb with goblet cells or crowded with papillae

Special stain	Mucin -	PAS+, mucin -	Mucin +
Amylase content	High	Low	Low
CEA	Low	Low	High
CEA, carcinoembryonic antigen.			

P.1439

Ancillary Procedures in the Identification of Cystic Lesions

As mentioned above, a number of biochemical tests and radioimmunoassays on aspirated fluids may assist in the classification of cystic lesions. The most common procedure is to determine the levels of **CEA**, which is elevated in neoplastic cysts but is low in pseudocysts (Lewandrowski et al, 1993; Centeno et al, 1994, 1997). Pinto and Meriano (1991) noted that the highest level of CEA is observed in cystic carcinomas and mucinous cysts. On the other hand, the **amylase** content is high in pseudocysts and absent or very low in neoplastic cysts. Additional data on the differential diagnosis of principal cystic lesions of the pancreas are summarized in Table 39-2.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms (IPMNs) occur more frequently in males than in females (Yamada et al, 1991; Madura et al, 1997). They arise from the main pancreatic duct, or its major branches, causing cystic dilatation of the duct. The obstruction of the duct system is caused by papillary epithelial proliferation, and variable degrees of mucin hypersecretion. IPMNs are also divided into **benign, borderline, and malignant noninvasive or invasive lesions**. Histologically, the neoplastic cells are usually tall, columnar, and mucin-containing, forming long, graceful papillary projections (Fig. 39-9). The noninvasive tumors are confined to the duct. It is not possible to cytologically distinguish between mucinous cystic tumors (described above) and intraductal papillary mucinous tumor. This distinction was not made histologically until a decade ago (Anonymous, 1996; Kloppel et al, 1996; Solcia et al, 1997). We recently encountered several such lesions in FNA, all of which were incidental CT scan findings. In adequate smears, benign, borderline, and malignant tumors can be predicted. Otherwise, mucinous cystic neoplasms on FNA should be reported with care. All benign and borderline lesions are curable by resection (see review by Warshaw et al, 2003).

Figure 39-9 Intraductal papillary mucinous carcinoma. *A-C.* Thick clusters of tumor cells in a papillary (*B*) or disorderly (*C*) arrangement. Note the nuclear abnormalities. *D.* Histology of the tumor shown in *B* and *C*. There is an intraductal proliferation of neoplastic glands, with superficial invasion of the wall of the duct.

CARCINOMA

Carcinoma is the most frequent space-occupying neoplastic lesion of the pancreas. Other neoplastic lesions are relatively uncommon. In the United States, pancreatic cancer is the third most common malignant tumor of the gastrointestinal tract, and the fifth leading cause of cancer-related mortality (Jemal et al, 2002). The disease is significantly more frequent in North America, Europe, and Russia than in South Asia and Africa (Hamilton and Aaltonen, 2000).

Patients

P.1440

with pancreatic carcinoma are usually in their fifth to seventh decade of life, and the male-to-female ratio is almost equal. There are no known **etiologic environmental factors**, although associations with cigarette smoking, highfat diet, diabetes mellitus, and industrial pollutants have been reported (Cubilla and Fitzgerald, 1978; Malagelada, 1979; Warshaw and Fernandez-del Castillo, 1992). Alcoholism and coffee drinking have been implicated and refuted (Wynder, 1973; Cubilla and Fitzgerald, 1978; Malagelada, 1979; Warshaw and Fernandez-del Castillo, 1992). Although pancreatic carcinoma and chronic pancreatitis are commonly associated, the nature of their relationship is controversial. An increased risk has been observed in patients with **hereditary pancreatitis** (Lowenfels et al, 1997).

The prognosis is dismal, with estimated annual deaths in the United States (28,900) closely approaching the estimated annual incidence of 29,200. Nearly all patients die within 2 years following the diagnosis. Only about 5% to 10% of all pancreatic ductal cancers are considered resectable at diagnosis (Warshaw and Swanson, 1988).

About 90% of these tumors are **carcinomas of ductal origin** that are histologically similar to carcinomas of the biliary tree (see Chap. 24). More than one half of ductal carcinomas are located in the **head of the pancreas** (Solcia et al, 1997) and they may invade and compress the pancreatic and common bile ducts, causing **obstructive jaundice and a distended**

palpable gall bladder (sign of Courvoisier). The classic **clinical triad** of symptoms of pancreatic carcinoma (jaundice, weight loss, and pain radiating to the back) is nonspecific. Gallstones obstructing the common bile duct, chronic fibrosing pancreatitis, or other malignant tumor in the area of the porta hepatis, whether primary or metastatic, have a very similar clinical presentation.

In contrast, **carcinomas of the body or tail of the pancreas are insidious**, rarely produce early symptoms, and are usually discovered in a more advanced stage. Approximately 10% of patients present with **peripheral migratory deep vein thrombosis or thrombophlebitis (Trousseau's syndrome)**, which is attributed to the release of platelet aggregating factors and procoagulants from the tumor or its necrotic products. This phenomenon is occasionally encountered with other visceral tumors, such as carcinomas of the stomach, colon, ovary, or lung (Moossa, 1982). At the time of diagnosis, peripancreatic, celiac, and porta-hepatis lymph nodes are involved in 85% of the patients, accounting for the dismal prognosis. Distant metastasis occurs primarily to the liver and lungs, and less often to bone.

Ductal Adenocarcinoma

Cancers of the pancreatic ducts are adenocarcinomas with varying degrees of differentiation. On gross examination, ductal carcinoma usually appears as a poorly defined, pale hard mass. The American Joint Committee on Cancer (Alberos-Saavedra et al, 1999; AJCC, 2002) recognizes **four histologic grades based on differentiation**: (1) well-differentiated, (2) moderately differentiated, (3) poorly differentiated, and (4) anaplastic or undifferentiated. This classification has not been very helpful in practice because, as noted above, the vast majority of patients die within 2 years of diagnosis regardless of tumor grade.

Well-Differentiated Ductal Carcinoma

Histology

Well-differentiated ductal adenocarcinomas are composed of neoplastic ducts of irregular shapes and sizes, separated by a variable amount of stroma (Fig. 39-10B). Nearly identical tumors may be primary in the bile ducts or the gall bladder. The tumor cells lining the neoplastic ducts are cuboidal or columnar in shape, and show relatively limited nuclear abnormalities in the form of enlargement and visible nucleoli.

Cytology

The smears of well-differentiated adenocarcinomas are often rich in epithelial cells. The smear background is usually clean, and mucus may be apparent. Characteristically, the cancer cells form **large, thick clusters and occasionally three-dimensional papillary groups** (Fig. 39-10A). Tumor cells may also occur **in flat sheets** with a "honeycomb" arrangement of cells (Fig. 39-10C). Dispersed cancer cells may also occur (Fig. 39-10D). Although the nuclei are generally **uniform**, on average they are **twice the size of normal duct cell nuclei**. Therefore, identifying an occasional cluster of benign ductal cells in the same smear allows a comparison of nuclear sizes (Fig. 39-11A). Although the **nuclei of cancer cells** are usually spherical or oval, with only subtle nuclear membrane abnormality and finely granular chromatin, **the nucleoli** are always larger than in benign cells (see Fig. 39-10C,D). In the **honeycomb type of clusters** with sharply outlined cells borders, closely resembling normal ductal cells, the **spacing of cancer nuclei is not equidistant**, because some nuclei touch and overlap each other. This is sometimes the only recognizable criterion of a very well-differentiated

adenocarcinoma. The presence of **rare mitotic figures** and scattered pleomorphic cancer cells is strongly suggestive of a malignant tumor.

Some observers have attempted to introduce the terms **high- and low-grade dysplasia** to characterize cytologic changes in **brushings** of the pancreatic ducts that do not fully meet the criteria of ductal carcinoma (Layfield et al, 1995), in particular the absence of single cancer cells. In the study by Layfield et al (1995), half of the patients with “low-grade dysplasia” and nearly all patients with “high-grade dysplasia” showed evidence of pancreatic cancer. Thus, we believe that the introduction of the term “dysplasia” in pancreatic cytology is not helpful.

The important features in differentiating between benign duct cells and cells of well-differentiated adenocarcinoma are summarized in Table 39-3.

Moderately and Poorly Differentiated Ductal Carcinoma

Histology

In tissue sections of a **moderately differentiated** pancreatic duct carcinoma, much of the tumor is composed of neoplastic

P.1441

glands and **complex tubular or acinar structures**, which are usually surrounded by dense connective tissue stroma (Albores-Saavedra et al, 1999). The **cells lining the glands are much larger than normal ductal cells**, have high nucleocytoplasmic ratios and loss of polarity, and thus are easily recognizable as malignant, in contrast to well-differentiated carcinoma or chronic fibrosing pancreatitis (Fig. 39-11D). **Perineural invasion** is common in carcinoma, as are mitoses and necrotic debris in the lumens of neoplastic glands. The tumor may be **surrounded by a broad zone of chronic pancreatitis** that may be the target of a misplaced FNA, leading to a “false-negative diagnosis.”

Figure 39-10 Ductal adenocarcinoma, well-differentiated type. *A.* Cell cluster with nuclear crowding and pleomorphism. Note the presence of nucleoli. *B.* Histology of the tumor shown in *A* (peritoneal implant biopsy). *C,D.* An extremely well-differentiated ductal adenocarcinoma mimicking benign ductal epithelium. The cell cluster in *C* mimics benign ductal epithelium, except for the nuclear hyperchromasia and nucleoli. *D.* Loosely

arranged, enlarged, granular nuclei, some containing small nucleoli. Very subtle nuclear contour abnormality and inconspicuous nucleoli are the key to the diagnosis.

The relatively uncommon **poorly differentiated tumors** are composed of glands, and solid sheets and cords of tumor cells (Albores-Saavedra et al, 1999). The cancer cells composing these tumors are pleomorphic and may form abortive glands (Fig. 39-12B).

Cytology

In FNA smears, the cells of moderately differentiated pancreatic carcinoma are easily **recognized as malignant**. The comparison of these cells with fortuitous normal ductal cells in the same smear enhances the differences (Fig. 39-11A). Most of the tumor cells show some evidence of **glandular or acinar differentiation** in the form of cohesive or three-dimensional, smooth-edged cell clusters and transparent and sometimes vacuolated cytoplasm (Fig. 39-11B). Most of the large **nuclei** are relatively uniform and ovoid in shape, with **large, prominent nucleoli**. However, scattered **markedly enlarged pleomorphic nuclei**, often stripped of cytoplasm or surrounded by cytoplasmic debris, are often seen (Fig. 39-11C). Nuclear crowding, molding, and overlapping are common features in cell clusters.

Poorly differentiated duct carcinomas are characterized by loosely structured cell clusters and dispersed, **highly pleomorphic, sometimes multinucleated malignant cells** of variable size and nuclear and nucleolar configuration (Fig. 39-12A,B). However, when the multinucleated giant cancer cells form the predominant cell population, a diagnosis of **anaplastic carcinoma of giant-cell type** should be considered (see below). The correlation of cytology and histology in this group of tumors is poor because many of these patients are considered inoperable once the aspirate confirms the clinical suspicion of cancer.

With the use of multivariate logistic-regression analysis,

P.1442

Robins et al (1995) examined 19 cytologic criteria that are helpful in interpreting FNA smears in pancreatic adenocarcinoma. **Nuclear crowding and overlapping, nuclear contour abnormality, and irregular chromatin distribution** were considered the key criteria of diagnosis. **Nuclear enlargement, single epithelial cells, necrosis, and mitotic activity** were listed as the second tier of diagnostic criteria. The application of these criteria resulted in a diagnostic improvement in 70% to 100% of pancreatic cancers. We consider the presence of clearly visible **nucleoli** to be an important diagnostic criterion in the diagnosis of pancreatic duct carcinoma. Still, the FNA smears in pancreatic cancer

P.1443

do not always conform to established patterns. Experience in interpreting this material is essential.

Figure 39-11 Moderately differentiated ductal adenocarcinoma. *A.* Benign ductal cells (top right) in marked contrast to abnormal cells from moderately differentiated ductal adenocarcinoma. *B.* Cohesive and three-dimensional groups of large glandular cells with transparent and vacuolated cytoplasm, nuclear pleomorphism, and prominent nucleoli. *C.* Pleomorphic single cancer cells stripped of cytoplasm, surrounded by cytoplasmic debris, are an indication of less well-differentiated adenocarcinoma. *D.* Histology of the moderately differentiated ductal adenocarcinoma.

TABLE 39-3 PRINCIPAL FEATURES DIFFERENTIATING BENIGN BUT ATYPICAL DUCTAL EPITHELIAL CELLS FROM WELL-DIFFERENTIATED PANCREATIC DUCT CARCINOMA

	Benign Ductal Cells	Well-Differentiated Carcinoma
Number of clusters	Few	Often numerous
Configuration of clusters	Compact monolayer with uniformly spaced nuclei (polarity maintained)	Compact monolayer with some nuclei in touch with each other (loss of polarity)
Size of cells/nuclei	Normal	Enlarged (twice the normal size)
Nuclear membrane	Smooth	Irregular
Nucleoli	Tiny, barely visible	Small, sometimes multiple readily

		visible
Single large, abnormal cells	Absent	Present
Individual cells with mucin vacuole	Absent or rare in chronic pancreatitis	Often present

Figure 39-12 Poorly differentiated ductal adenocarcinoma. *A.* Highly pleomorphic malignant cells with transparent cytoplasm and prominent nucleoli. *B.* Histology of a poorly differentiated adenocarcinoma forming abortive glands.

Variants of Duct Carcinoma

Undifferentiated (Anaplastic) Carcinoma

There are two distinct histologic variants of anaplastic or undifferentiated pancreatic carcinoma: a **giant-cell type** and **small-cell type**. These tumors constitute 2% to 7% of ductal carcinomas. Both tumor types are highly aggressive, with a median survival of only 2 months (Hamilton, 2000).

Giant-Cell Variant of Undifferentiated (Anaplastic) Carcinoma

The **giant-cell variant** has been variously called **pleomorphic carcinoma**, **sarcomatoid carcinoma**, or **spindle and giant-cell carcinoma**. Immunohistochemical studies have demonstrated its epithelial origin, partially with mesenchymal differentiation (Hoorens et al, 1998). The distribution by age and sex is similar to that of ductal cancers. However, **the tumor is larger in size** at the time of diagnosis (median diameter = 11 cm) and **more often is located in the body or tail of the pancreas** (Cubilla and Fitzgerald, 1984). On gross examination, hemorrhage, necrosis, and cystic degeneration are common, and extensive nodal metastases are usually present.

Histology

The histology is that of a clearly malignant tumor with variable numbers of **pleomorphic tumor giant cells and spindle cells** with scanty supporting stroma, sometimes with a striking **inflammatory cell infiltrate**. The giant cells have multiple hyperchromatic nuclei and prominent nucleoli. Spindle cells may occasionally constitute virtually all of the tumor, which may be mistaken for a sarcoma. When multiple sections of anaplastic carcinoma are examined, areas of ordinary ductal adenocarcinoma with evidence of intracytoplasmic mucin production are nearly always found.

Cytology

The cytology of the giant-cell carcinoma is quite distinctive. The aspirate is composed of many **dispersed, huge, multior mononucleated tumor cells** in a richly cellular smear (Fig. 39-13A,B). The background may include inflammatory cells. Sometimes spindle cells predominate. The tumor cells may have a thick, well-defined eosinophilic cytoplasm that is suggestive of keratinization (Fig. 39-13C). A **metastatic giant-cell carcinoma of the lung to the pancreas** has an identical cytomorphology but a different clinical presentation, with a pulmonary mass. Giant-cell tumors of other organs, such as the thyroid and malignant fibrous histiocytoma, must also be considered in the differential diagnosis.

Carcinoma With Osteoclast-Like Giant Cells

Carcinoma with osteoclast-like giant cells is an extremely rare pancreatic cancer in which **osteoclast-like multinucleated giant cells** are numerous. These cells are most likely reactive and not neoplastic, and are usually, but not always, concentrated near regions of hemorrhage, osseous metaplasia, or calcification. In aspiration smears, this tumor is characterized by the presence of **osteoclast-like giant cells with numerous small nuclei of approximately equal sizes, next to more conventional mono- and multinucleated cancer cells** (Koss et al, 1992). A few such cases have been reported in the cytologic literature (Walts, 1983; Mancini et al, 1985). The immunocytologic features and the differential diagnosis of these rare tumors were discussed by Mullick and Mody (1996).

Small-Cell Variant of Undifferentiated (Anaplastic) Carcinoma

Histology

The small-cell variant of pancreatic carcinoma, sometimes called round-cell anaplastic-type carcinoma, is exceedingly rare (<1%) and the histology is identical to that of small-cell carcinoma of the lung (see Chap. 20 and Fig. 39-14C). **Small-cell lung cancer with metastases** to the pancreas is by far more common than a primary pancreatic tumor of this type, and should be the first diagnostic choice until proved otherwise, particularly in patients with evidence of a lung lesion.

Figure 39-13 Undifferentiated (anaplastic) carcinoma. *A,B.* Giant-cell variant. The aspiration smear contained very large, dispersed, and pleomorphic malignant cells, some of which were multinucleated. *C.* Spindle cell variant. Many of the multinucleated pleomorphic cancer cells are spindly and have an eosinophilic cytoplasm, suggestive of keratin formation. (*B:* Diff-Quik.)

Figure 39-14 Undifferentiated (anaplastic) carcinoma, small-cell variant. *A,B.* Dispersed small malignant cells with scanty cytoplasm, nuclear molding, and single cell necrosis. This diagnosis can be made only in the absence of a pulmonary primary cancer (see text). *C.* A needle core biopsy of the pancreas confirmed a small-cell variant of undifferentiated carcinoma. The nuclear DNA lining a vessel (Azzopardi phenomenon) is rare but characteristic.

Cytology

The tumor sheds sheets of small cancer cells with very scanty cytoplasm. Necrosis of the tumor cells is common (Fig. 39-14A). When they are well preserved, the tumor cells form single files with nuclear molding (Fig. 35-14B). The differential diagnosis includes malignant lymphoma and neuroendocrine carcinoma of the pancreas. It is usually possible to distinguish between these tumor types based on cytologic features (see below). If the tumor type is in doubt, and additional smears or cell blocks are available, specific immunocytochemical stains for lymphocytes (CD-45) and neuroendocrine carcinoma (such as chromogranin) are of diagnostic value.

Adenosquamous and Squamous Carcinoma

Adenosquamous carcinoma is a rare variant of pancreatic ductal carcinoma that occurs in 3% to 4% of patients with pancreatic carcinoma (Cubilla and Fitzgerald, 1984). The tumor is characterized by the synchronous presence of **poorly formed glands and islands of squamous cancer cells in varying proportions** (Fig. 39-15B).

In FNA smears, these tumors are often diagnosed as poorly differentiated ductal carcinoma (described above) because the **squamous component is either absent or very scanty**. When present, the cells of the squamous component usually have the features of a well-differentiated squamous cancer, with **hyperchromatic, pyknotic and angulated nuclei**, and **dense, sometimes keratinized cytoplasm** (Fig. 39-15A).

Primary pure squamous cell carcinoma of the pancreas is exceedingly rare. This diagnosis can be considered only after metastases from lung, esophagus, and head and neck sites have been ruled out. The **cytology** is clearly that of a squamous carcinoma, and the tumor cells may be highly pleomorphic and spindly.

Other Uncommon Variants of Ductal Carcinoma

Colloid (mucinous noncystic) carcinoma, also referred to as a **gelatinous carcinoma**, is classified as a separate entity in histopathologic classifications (Kloppel et al, 1996; Hamilton and Aaltonen, 2000). These very uncommon pancreatic tumors are similar to ductal carcinomas in terms of age and sex distribution. Histologically, this tumor is identical to tumors of the stomach and other organs, and is characterized by **isolated cells and groups of vacuolated cells floating in pools of mucin**. **Pseudomyxoma peritonei** has been described as a complication of this tumor (Chejfec et al, 1986). The cytologic presentation is similar to colloid carcinoma of the breast and stomach (see Chaps. 24 and 29). Three-dimensional groups of vacuolated cells float in abundant mucin with a clean background (Fig. 39-16A,B). It may not be possible to distinguish between frankly malignant intraductal papillary cystic tumors and mucinous cystadenocarcinoma in FNA material.

Figure 39-15 Adenosquamous carcinoma. *A.* Poorly differentiated adenocarcinoma and less cohesive keratinizing small squamous cancer cells are adjacent to each other. *B.* Histology of an adenosquamous carcinoma.

Signet ring cell carcinoma of the pancreas is extremely rare (Solcia et al, 1997). A metastasis from a gastric primary must be considered before this diagnosis is made (see Chap. 24 for a description of cytology of signet ring carcinoma).

Cubilla (1984) and Kanai (1987) described primary **clear-cell carcinoma** of the pancreas. In a recent case seen by us, a multifocal clear-cell carcinoma involving the pancreas proved to be **metastatic renal carcinoma** (see Chap. 40). The patient had undergone a left nephrectomy for clear-cell carcinoma 2 years earlier and developed pancreatic metastasis soon after.

Oncocytic carcinoma is an exceptional form of ductal carcinoma that was first described by Huntrakoon (1983). It is not clear whether this **clearly malignant tumor** is somehow related to the endocrine tumors with an oncocytic component (Radi et al, 1985). The solid tumor is composed of **large cells with markedly eosinophilic and granular cytoplasm** that on electron microscopy shows the presence of **packed mitochondria** (Thompson et al, 1998). Several descriptions of the cytologic presentation of primary and metastatic tumors with oncocytic features (some expressing endocrine markers) have been published. The cytologic presentation of oncocytes is repeatedly discussed in the appropriate chapters (also see below).

Ancillary Tests for the Diagnosis of Pancreatic Duct Carcinoma

Pinto et al (1997) documented that **mutations of the Kras gene, as determined by polymerase chain reaction**

P.1446

(PCR), combined with **elevated levels of carcinoembryonic antigen**, as determined by radioimmunoassay, were practically diagnostic of pancreatic carcinoma, even in FNAs that were not conclusive.

Figure 39-16 Colloid (mucinous noncystic) carcinoma. *A,B.* Papillary clusters of malignant glandular cells floating in a pool of mucin. These tumors are often reported as papillary mucinous adenocarcinomas.

As of this writing, no specific immunohistochemical or serological marker for pancreatic carcinoma is available.

Acinar Cell Carcinoma

The acini accounts for 80% of the pancreatic mass. However, acinar cell carcinomas are rare, comprising no more than 1% to 2% of all pancreatic neoplasms (Klimstra et al, 1992; Hoorens et al, 1993). They occur at any age, the median being 51 years, with a slight male preponderance. The symptoms are nonspecific. Rarely, acinar cell carcinoma is **functional**, causing disseminated fat necrosis, polyarthralgia, and eosinophilia resulting from the release of pancreatic digestive enzymes (MacMahon et al, 1965). The prognosis is poor, with a 10% 5-year survival (Klimstra et al, 1992; Hoorens et al, 1993).

Histology

The histology of acinar cell carcinoma is distinctive, with either an **acinar pattern**, resembling normal pancreatic acini, or a **solid pattern**, mimicking the solid variant of endocrine tumors of the pancreas (Fig. 39-17D).

Cytology

FNA cytology of these uncommon tumors is similar to that of **acinic cell carcinoma of the salivary glands** (see Chap. 32), and is characterized by the presence of **cohesive groups of uniform, small tumor cells with granular eosinophilic to purple cytoplasm forming imperfect acini** (Fig. 39-17A-C). Cytoplasmic granules may be better documented in air-dried smears stained with one of the hematologic stains (Samuel and Frierson, 1996). There is a striking resemblance to normal acinar cells. However, the **tumor cell nuclei are larger, more crowded, and may contain visible nucleoli**. The aspirate is generally devoid of ductal cells. Immunocytochemical **stain for trypsin is usually positive, whereas mucin stain is negative**. These two features are helpful in distinguishing acinar cell carcinoma from ductal and endocrine tumors. Labate et al (1997) compared the cytology of acinar carcinoma with that of islet cell tumors, and, predictably, found very limited similarity between the two.

Pancreatoblastoma, an extremely uncommon tumor that occurs mainly in children, is the only other pancreatic tumor that is somewhat similar in morphology to acinar carcinoma (see below).

ENDOCRINE TUMORS OF PANCREAS (ISLET CELL TUMORS AND CARCINOIDS)

Islet cell tumors are comparatively rare pancreatic neoplasms that are most commonly, but not exclusively, located in the **body or tail of the pancreas**. Because of their unpredictable behavior, the term **pancreatic endocrine neoplasm** has been widely embraced. They occur in all age groups, can be multiple, and account for 2% to 3% of all pancreatic neoplasms (Solcia et al, 1997). However, clinically occult, usually small islet cell tumors are found in about 1% of pancreases examined at autopsy (Mukada and Yamada, 1982). The endocrine tumors may be

solid or, rarely, cystic. They may arise from **any of the subtypes of islet cells** and may be hormonally active. The syndromes associated with pancreatic endocrine neoplasms are listed in Table 39-4. These tumors may also produce **adrenocorticotrophic hormone (ACTH), parathyroid-like hormone, calcitonin, growth hormone-releasing hormone, and human chorionic gonadotropin** (Wilson et al, 1991). **Metastases to the pancreatic lymph nodes, liver, and other organs** may be seen at the time of diagnosis, but even then the tumors may behave in an indolent fashion, with longterm survival.

In patients with **multiple endocrine neoplasia (MEN) type I**, it is not uncommon for islet cell tumors to be associated with endocrine neoplasms of other organs, such as pituitary and parathyroid adenomas, and, less commonly, the thymus, lung, thyroid gland, and adrenal gland (Donow et al, 1991).

P.1447

For further discussion of MEN, see Chapter 7 and chapters discussing endocrine neoplasms of other organs.

Histology

Three principal microscopic patterns are seen singly or in combination: **the solid or diffuse pattern**, the **ribbon-like or trabecular pattern (gyriform pattern)**, and the **acinar or rosette-like pattern (glandular pattern)** (Figs. 39-18D and 39-19C). Numerous capillary blood vessels are closely associated with tumor cells. Connective tissue septa usually subdivide these tumors into distinct territories. Because of their extensive vascular network, necrosis is very rare, even when these tumors are relatively large in size. Attempts have

P.1448

been made to correlate the microscopic features of these tumors with their hormonal activity,

with only moderate success (Oertel et al, 1999). Regardless of the histologic pattern, the vast majority of tumor cells in a given tumor are **uniform in appearance** and composed of **cuboidal and sometimes spindly small- to medium-sized cells**, measuring 15-20 μm in diameter. Rarely, **scattered single large cells with large hyperchromatic atypical nuclei** occur among the small tumor cells (Fig. 39-20D). Electron microscopy demonstrates dense core cytoplasmic neurosecretory granules. With the use of special stains, specific secretory products (e.g., insulin and gastrin) may be documented in islet cell tumors (Table 39-4).

TABLE 39-4 ISLET CELL TUMORS AND ASSOCIATED CLINICAL SYNDROMES

Type of Cell	Hormone Produced	Clinical Manifestation
Alpha (α) cells	Glucagon (glucagonoma)	Hyperglycemia
Beta (β) cells	Insulin (insulinoma)	Hypoglycemia
Delta (δ) cells	Somatostatin (somatostatinoma)	Usually nonfunctioning
G cells	Gastrin (gastrinoma)	Zollinger-Ellison syndrome* (intractable gastric/duodenal ulcer)
VIP cells	Vasoactive intestinal polypeptides (vipomas)	Severe watery diarrhea
PP cells	Pancreatic polypeptides	Rarely produce symptoms

* May also be caused by nests of endocrine cells located in the gastric antrum and duodenal mucosa (Bhagavan et al. Arch Pathol 98:217-222, 1974).

Figure 39-18 Neuroendocrine tumor of the pancreas. *A,B.* Small, well-preserved monomorphic cells anchoring on thin-walled branching vessels. *C.* Uniform, dispersed, ovoid small cells with scanty cytoplasm and “salt and pepper” chromatin. Note the eccentric position of the nuclei in many of the tumor cells. *D.* Histology with an acinar and rosette-like pattern.

Pancreatic **carcinoid tumors**, which arise from the neuroendocrine (Kulchitsky) cells in the base of the pancreatic ductal mucosa, are identical to islet cell tumors (Lozowski et al, 1979; Khorsand et al, 1987). The carcinoid tumors are **strongly argyrophilic** (e.g., positive Grimelius stain) and show **chromogranin** granules (see Fig. 39-19B). **Serotonin** may be documented in the cytoplasm of these tumor cells, and may cause **carcinoid syndrome**.

Endocrine Tumors With an Oncocytic Component

As in the lung, **carcinoid tumors with a prominent oncocytic component** have been described (Radi et al, 1985). In some cases, the oncocytic component is dominant and the tumors are classified as **oncocytomas that express endocrine function** (Nguyen et al, 1992; Pacchioni et al, 1994). It is not clear whether these tumors are related to the oncocytic type of ductal carcinoma, but some of them may form metastases.

Cytology

As a rule, aspirates of pancreatic endocrine tumors are **richly cellular**, yielding numerous dispersed, predominantly **monomorphic cells** that appear **singly or form small, loosely structured groups, chains, or rosette-like clusters** (see Figs. 39-18, 39-19 and 39-20). The background of the smears is usually clean and free of necrotic material or cell debris. Tumor cells may be observed **anchoring on thin-walled branching blood vessels** (see Fig. 39-18A,B). This feature, when present, is helpful in distinguishing pancreatic endocrine tumors from metastatic small-cell lung cancer, lymphomas, and other small-cell malignant tumors, which are not particularly rich in capillaries. On the other hand, a solid pseudopapillary tumor of the pancreas may be rich in capillary vessels in aspirated samples (see below and Fig. 39-21A,B).

The tumor cells are generally **small (about three times**

the size of lymphocytes) and usually show little pleomorphism (see the exception below). The tumor cells are **uniformly well preserved** (unlike lymphoma and small-cell carcinoma), are usually **round, oval, or polygonal**, and rarely cylindrical. The **faintly eosinophilic or basophilic cytoplasm is usually scanty but clearly visible**. The **nuclei** of pancreatic neuroendocrine carcinoma are spherical, show a “**salt and pepper**,” finely granular texture, and **small but clearly visible, usually single nucleoli**. There is no nuclear molding.

Eccentric location of the nuclei within the oval cytoplasm is commonly seen, giving some of these cells a “plasmacytoid” appearance that in some cases may be pronounced (see Fig. 39-19A). Still, the configuration of the tumor cells and the presence of nucleoli are not consistent with a plasmacytoma. Although nuclear sizes may differ from tumor to tumor, the hallmark of these tumors is the uniformity in the size and shape of the nuclei in any given tumor. **Mitotic figures are very rare**. The presence of tumor necrosis and numerous mitotic figures is not consistent with an endocrine tumor because these features are more likely to be seen in anaplastic (small-cell) carcinoma, as described above. **Stellate, crystal-like deposits of amyloid** may be observed in some tumors (Tischler and Campagno, 1979); however, their presence in cytologic material has not yet been reported.

Figure 39-19 Neuroendocrine tumor. *A.* Neuroendocrine tumor with a plasmacytoid appearance of the large cells. The cytoplasm is abundant, pink, and granular. The nuclei, with prominent nucleoli, are eccentric in position. *B.* The positive chromogranin stain in cytologic smear confirms the diagnosis of a neuroendocrine tumor. *C.* Histology of a neuroendocrine tumor with a solid or diffuse pattern.

In a case of neuroendocrine carcinoma described by Koss et al (1992), the smears contained **scattered, giant cells, some of which had markedly hyperchromatic, opaque large nuclei** (see Fig. 39-20C). Similar cells were observed in the tissue sections of the resected tumor (see Fig. 39-20D). The presence of scattered, markedly abnormal, large cells may also be observed in other endocrine tumors, such as medullary carcinoma of the thyroid, carotid body tumors, or carcinoids. Their presence has no bearing on the behavior of the tumor or prognosis. The principal features of endocrine tumors are summarized in Table 39-5.

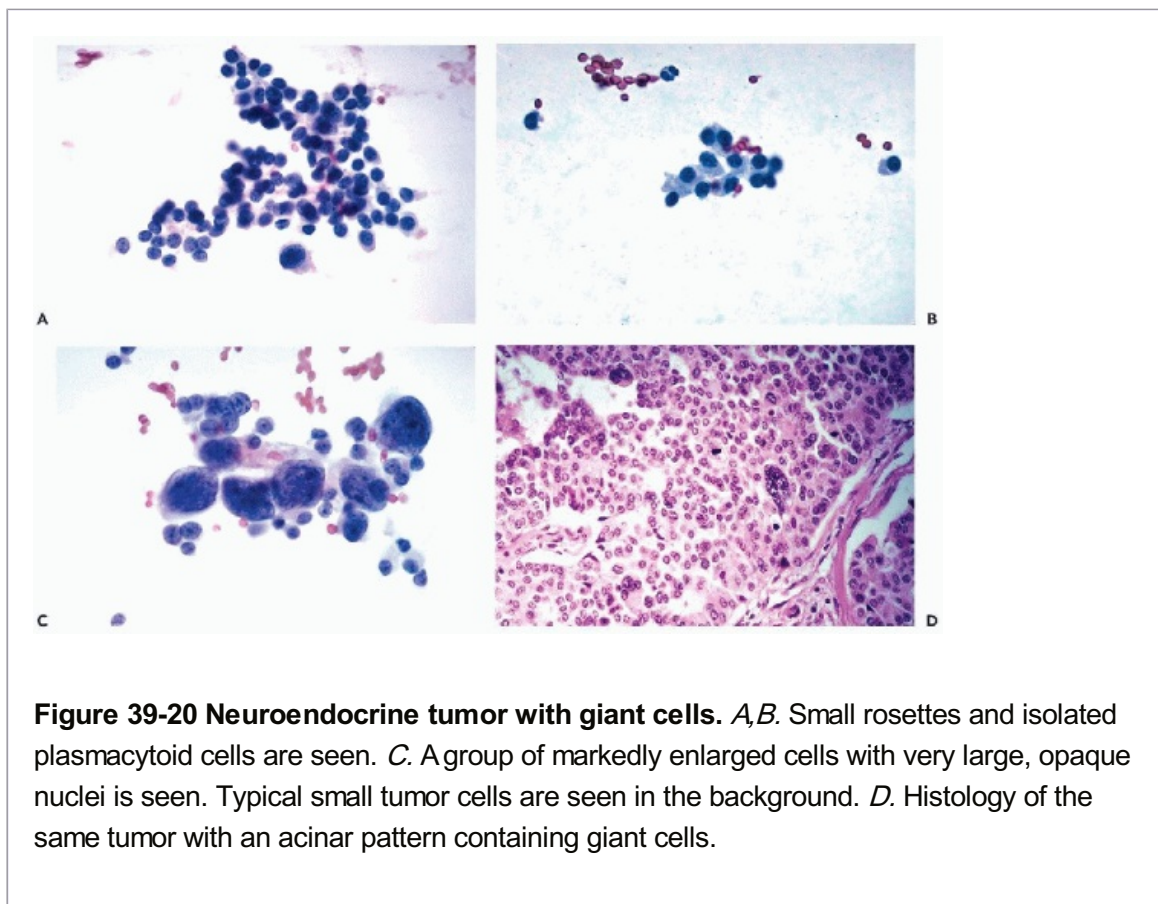

We have observed an example of a **slowly growing cystic endocrine tumor of the pancreas**. Several aspirates of cyst fluid were noncontributory. Finally, **the diagnosis could be established by an aspiration of the wall of the cyst, an essential procedure in FNA of cystic lesions that do not collapse after aspiration.**

Several descriptions of the cytology of **endocrine pancreatic carcinomas with an oncocytic component** have been published (Bondeson et al, 1990; Nguyen-Ho et al, 1994; Pacchioni et al, 1996; Thompson et al, 1998). The presence of **large eosinophilic cells with dense nuclei and markedly eosinophilic, granular cytoplasm** is the hallmark of these tumors. Similar tumors may be observed in the lung (see Chap. 20). Benign oncocytomas are observed in many other organs, as discussed in Chapters 30, 32, and 40. However, the pancreatic tumors of this type are **malignant and fully capable of metastasizing** (Thompson et al, 1998).

The differential diagnoses of pancreatic neuroendocrine tumor in **metastatic sites**, such as liver or lymph nodes, must include morphologically identical intestinal and pulmonary carcinoids. In a functioning islet cell tumor, **immunocytochemistry**

P.1450

performed for specific hormones on cell blocks or smears is usually rewarding and correlates well with the patient's symptoms (see Table 39-4). Otherwise, the differential diagnosis must be based on clinical and radiologic findings, which are always helpful in difficult diagnostic situations.

Islet cell hyperplasia may be functionally active, but rarely forms visible or palpable tumors. In the exceptional cases of this entity reported in the cytologic literature, hyperplasia could not be distinguished from islet cell tumor (Nguyen, 1986). Endocrine tumors of the pancreas must be

distinguished from **acinar cell carcinoma, pancreatoblastoma, anaplastic small-cell carcinoma, malignant lymphomas, and small-cell tumors metastatic to the pancreas.** Excellent preservation of tumor cells (which is very unusual in other pancreatic tumors), a positive immunohistochemical stain (e.g., chromogranin on a smear or cell block), or, in some cases, electron microscopy can corroborate the diagnosis of endocrine tumor of the pancreas.

Excellent diagnostic results with transcutaneous or intraoperative cytologic recognition of endocrine tumors of the pancreas have been reported by al-Kaisi et al (1992), Saleh et al (1996), and Collins and Cramer (1996), corresponding with personal experience (Koss et al, 1992).

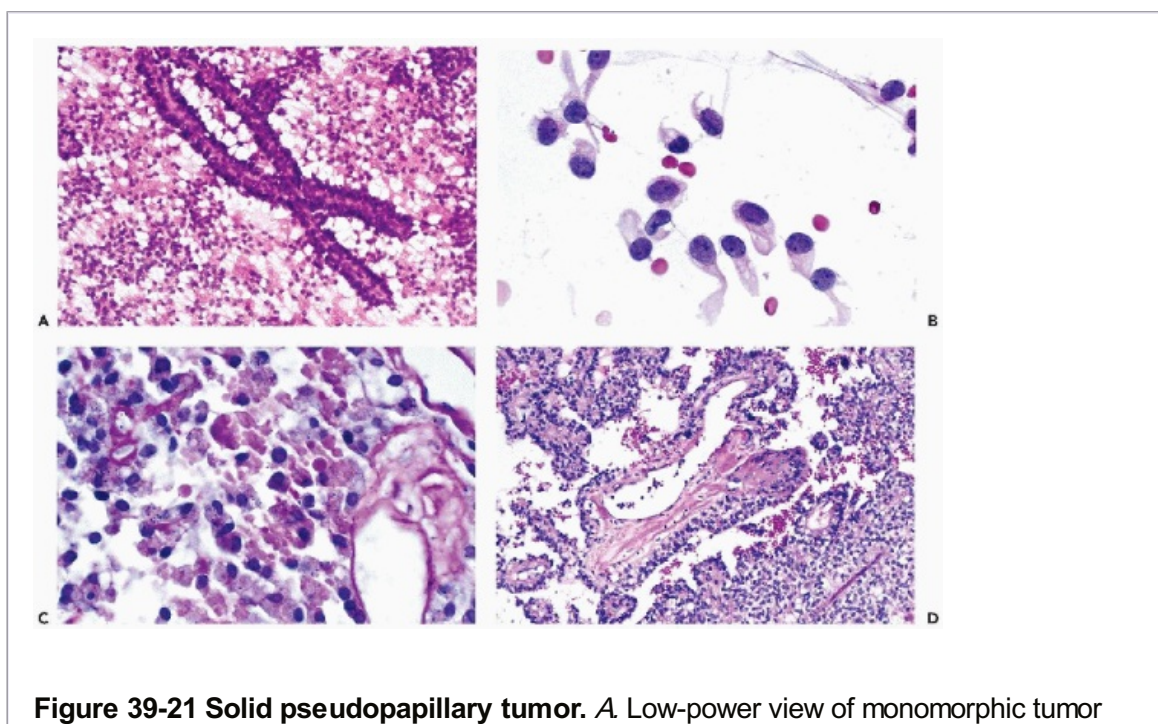

RARE EPITHELIAL NEOPLASMS

Solid Pseudopapillary Tumor

Although the solid pseudopapillary tumor is relatively rare, this is an interesting low-grade pancreatic carcinoma of unknown origin, with a unique cytomorphology. The tumor is also called **solid and cystic-papillary epithelial neoplasm (SPEN), Gruber-Frantz tumor, and papillary cystic neoplasm.** These tumors account for less than 3% of all nonendocrine pancreatic tumors (Morohoshi et al, 1983). The tumor usually affects **young women** in their twenties, although we have seen such a tumor in a teenage girl. Clinically, most patients present with vague upper-abdominal pain and a **palpable mass.** At the time of presentation, these tumors are large, with an average diameter of 11 cm, and most occur in the body and tail of the pancreas. Rarely, this tumor has been seen in an extrapancreatic location (Kloppel et al, 1991). Neither on gross examination nor on review of imaging studies do these tumors appear overtly cystic. Typically, they are encapsulated and soft, with a variegated tan cut surface showing cystic foci, hemorrhage, and necrosis. They are easily resectable and offer an excellent prognosis. Local invasion and infiltration of the capsule may occur, and while distant metastases are uncommon, some

P.1451

such cases have been reported (Capallari et al, 1990; Harisawa et al, 1995).

cells attached to cores of fibrovascular connective tissue (compare with Fig. 39-17A,B). *B.* The large tumor cells have long cytoplasmic processes with bland nuclei, some showing longitudinal grooves. *C.* Cell block stained with periodic acid-Schiff reagent (PAS) shows hyaline globules. *D.* Histology of the same tumor showing papillary features.

Histology

Microscopic examination reveals a variety of patterns: **solid papillary, trabecular, and cystic**. The **neoplastic cells are relatively uniform** throughout the tumor, **with long unipolar cytoplasmic processes anchoring to capillaries or forming pseudo-rosettes** (Fig. 39-21D).

TABLE 39-5 ESSENTIALS OF THE CYTOLOGIC DIAGNOSIS OF ENDOCRINE TUMORS OF THE PANCREAS

Dispersed tumor cells of medium size

Extreme uniformity of nuclei, with rare exceptions (giant nuclei may occur)

“Salt and pepper” chromatin

Sometimes plasmacytoid appearance

Absence of necrotic/pyknotic cells and nuclear molding

Positive endocrine stains (Grimelius or chromogranin) or ultrastructural evidence of neurosecretory granules

The oncocytic variant yields varying numbers of cells with granular eosinophilic cytoplasm, resembling Hürthle cells

Cytology

This unique and uncommon tumor has attracted a great deal of attention, as evidenced by numerous published case reports describing its unique histology and cytology (Alm et al, 1981; Bondeson et al, 1984; Chen et al, 1986; Foote et al, 1986; Frias-Hidvegi, 1988; Katz and Eyha, 1990; Jayaram et al, 1990; Mendonca, 1991; Geisinger and Silverman, 1992; Mandrekar et al, 1997). The FNA smears are often **richly cellular**, and at low magnification may show numerous **uniform tumor cells attached to** cores of fibrovascular connective tissue (Fig. 39-21A). This is the cytologic counterpart of the papillary fronds seen in histologic sections. This cell arrangement shows some similarity with neuroendocrine tumors of the pancreas. On closer scrutiny, however, the smears show **much larger uniform tumor cells with bland nuclei, sometimes with longitudinal grooves and elongated cytoplasmic processes** (Fig. 39-21B). Kashima et al (1997) observed the presence of **multinucleated giant tumor cells** in

one of their cases. **Cytoplasmic hyaline globules**, which stain with **periodic-acid-Schiff**

P.1452

(PAS), and **antibodies to alpha-1-antitrypsin and alpha-1-antichymotrypsin** may be observed (Fig. 39-21C). Remadi et al (1996) also reported a strong reaction of tumor cells with antibody to **progesterone**. Rarely, the cytoplasm contains clear vacuoles that do not contain mucin. Areas of cystic degeneration in the tumor are represented by foamy macrophages, giant cells, and debris.

Rarely, metastases do occur, and have been reported to show more cytologic atypia, including bizarre tumor cells and an increased mitotic rate (Cappellari et al, 1990).

Pancreaticoblastoma

Pancreaticoblastomas, also known as **infantile adenocarcinomas** of the pancreas, are uncommon tumors that occur mainly in infants and children, but also in adults (Klimstra et al, 1995). Histologically, the tumors are composed of **uniform, small epithelial cells arranged in sheets and nests** with well-formed **acinar structures and rosette formation**, suggestive of **endocrine differentiation**, which can be confirmed by neuroendocrine stains. The tumor cells, which contain eosinophilic or amphophilic cytoplasm, have central **round or ovoid nuclei** with visible **nucleoli**. When the differentiation is **acinar**, the usually cells contain cytoplasmic **zymogen granules**. Lipase, trypsin, and chymotrypsin have also been detected. **Squamoid corpuscles, composed of whorls of spindly, immature squamous cells**, may be present. The differential diagnosis includes other childhood blastomas, particularly Wilm's tumor arising from the left kidney. In adults, pancreatoblastoma may be **difficult to distinguish from endocrine tumor of the pancreas or acinar cell carcinoma without special stains**.

We have no personal experience with an aspirate of this rare childhood pancreatic tumor. However, the FNA cytology of one such tumor (in a 4-year-old boy) was described in great detail by Silverman et al (1990). In keeping with the histologic findings, the **tumor cells** were of oval configuration with **granular cytoplasm** and **nuclei with finely granular chromatin and small nucleoli**. Triangular and spindly cells were also seen, as well as **abundant stromal fragments**. Some of the cells **formed acinus- and rosette-like structures**. The dual exocrine and endocrine differentiation of the tumor was confirmed by ultrastructural and immunocytochemical studies. If such a cytologic pattern is observed in a child or young adult, it is likely that a cytologic diagnosis can be established. In an **adult**, the **possibility of an endocrine neoplasm** would have to be considered.

Figure 39-22 Metastatic tumors to the pancreas. A. High-grade lymphoma. Dispersed cells with convoluted nuclei and prominent nucleoli. B. Metastatic renal cell carcinoma of

the clear-cell type (see text).

PRIMARY MALIGNANT LYMPHOMAS

Primary malignant lymphoma of the pancreas is a rare disease, and only a handful of such cases have been recorded (Tuchek et al, 1993; Ezzat et al, 1996). Nearly all of these tumors are **non-Hodgkin's lymphomas** that may, clinically and on imaging, **mimic primary carcinomas**. A correct diagnosis can be life-saving and make an enormous difference in prognosis because these lymphomas show good response to chemotherapy (Fisher and Kabakow, 1987; Tuchek et al, 1993; Ezzat et al, 1996). Because of the rarity of primary pancreatic lymphomas, particularly in comparison with the **much higher frequency of metastatic lymphomas**, the cytologic experience apparently is limited to one case report of a large B-cell primary lymphoma, in which the diagnosis was established by transcutaneous FNA supplemented by immunocytologic analysis (Faulkner et al, 1998). The case was instructive because the tumor (in a 72-year-old man) was located in the head of the pancreas and caused obstructive jaundice, thus mimicking primary carcinoma of the head of the pancreas. The cytology of a metastatic lymphoma is illustrated in Figure 39-22A and also described in Chapter 31.

METASTATIC TUMORS TO THE PANCREAS

Metastatic cancers account for approximately 3% to 16% of all pancreatic malignant tumors (Matsukuma et al, 1997; Lampert et al, 1999). Metastases can occur from a wide

P.1453

range of sources, many of which are listed in Table 39-6. Malignant lymphoma may spread to peripancreatic lymph nodes and pancreas (see above). Benning et al (1992) pointed out that **many of these metastatic tumors may resemble primary carcinoma of the pancreas**. An example of metastatic renal carcinoma mimicking a clear-cell type of pancreatic duct carcinoma is shown in Figure 39-22B. Knowledge of the patient's history is extremely helpful in making the correct diagnosis.

TABLE 39-6 COMMON SOURCES OF VARIOUS CELL TYPES IN METASTATIC CANCER

Cell Types	Possible Primary Source Other Than the Pancreas
Squamous	Lung, head and neck, esophagus, cervix
Small cell	Lung, lymphoma, rhabdomyosarcoma, carcinoids
Clear cell	Kidney
Giant cell	Lung, thyroid, non-epithelial malignancy
Signet-ring cell	Stomach

Pigmented cell	Melanoma
----------------	----------

Figure 39-23 Metastatic rhabdomyosarcoma from the atrium of the heart of a 74-year-old patient. *A.* The aspiration smear shows a loose cluster of malignant cells with eosinophilic cytoplasm. *B.* Some of the tumor cells show a peripheral nucleus in cells with intensely eosinophilic cytoplasm, reminiscent of rhabdomyoblasts. *C,D.* Needle core biopsy of the heart with positive myoglobin stain in *D*, confirming the diagnosis of rhabdomyosarcoma.

The most difficult to recognize metastatic tumors to the pancreas are metastases from carcinomas of the gall bladder and extrahepatic biliary tract, because their morphology is identical to that of pancreatic ductal carcinoma. The presence of multiple tumor nodules, rather than a single lesion, and the absence of chronic pancreatitis are in favor of a metastasis. Unusual cell types encountered in aspirate smears of pancreas must prompt the question of organ of origin of these cells. Khalbuss et al (1999) have reported, from our institution, pancreatic metastasis from cardiac rhabdomyosarcoma, diagnosed by FNA of the left atrium in a 74-year-old woman (Fig. 39-23). The readers are referred to the appropriate chapters for discussion of the cytology of the various tumor types. Warranting a mention is **ectopic pancreas**, which may be mistaken for a metastatic tumor (Sams et al, 1990).

RESULTS AND CONCLUSIONS

Percutaneous FNA

Earlier reports showed that adequate diagnostic material was obtained in 60% to 90% of cases of pancreatic carcinoma

P.1454

(Goldstein et al, 1977; Tao et al, 1978; Itoh et al, 1979; Kolins et al, 1981; Mitty et al, 1981). Some of the early observers reported low sensitivity of the procedure (Alpern et al, 1985; Soudah et al, 1989). Somewhat better results were subsequently reported (Ekberg et al, 1988;

Welch et al, 1989; Robins et al, 1995). The results of transcutaneous aspiration for the diagnosis of pancreatic carcinoma are more accurate than those of pancreatic duct brushings (Layfield et al, 1995). Robins et al (1995) established a series of major and minor criteria for diagnosing ductal carcinoma that improved the recognition of pancreatic adenocarcinoma from 70% to 90%. The key problem is the difficulty of recognizing low-grade duct carcinoma (see above). Yang et al (1994) used Diff-Quik-stained smears to measure the diameter of the nuclei in various lesions, such as islet cell tumors and pancreatic carcinomas. Such measurements rarely help an experienced observer.

Some of the **reasons for poor performance of the percutaneous FNA of the pancreas are as follows:**

- The lesion is missed because of **imprecise localization and/or incorrect placement of the needle.**
- **Too much suction** is applied, resulting in bleeding and hemodilution of the sample, and interference with further sampling.
- **Inappropriate instrumentation**, notably **too thin or too long needles** that may be deflected by the abdominal wall and may be difficult to guide to a small lesion. **Needles larger than 22 gauge** are apt to cause vascular injury and collect cells extraneous to the pancreas.

In our experience, nearly all carcinomas of the pancreas can be identified by FNA, although occasionally the procedure must be repeated. **The presence of competent personnel in the radiologic suite, where most such procedures take place, is very helpful in establishing the adequacy of the sample while the patient waits. If the material is nondiagnostic, the aspiration can be repeated.**

Intraoperative Aspirations

A diagnosis of pancreatic carcinoma under visual control can be achieved in nearly 100% of cases (Hastrup et al, 1977; Stormby, 1979; Alpern et al, 1985; Soudah et al, 1989; Edoute et al, 1991; Blandamura et al, 1995; Saez et al, 1995). An important **pitfall** is the coexistence of carcinoma and pancreatitis. This may result in the aspiration of necrotic and inflammatory material, leading to a false-negative diagnosis. Less secure results are achieved in aspiration of cystic lesions, because the cyst content is not always representative of the nature of the cyst. **Aspiration of the wall of the cyst is always indicated.** A chemical analysis of the cyst fluid is sometimes diagnostically helpful, as discussed above.

The Kidneys, Adrenals, and Retroperitoneum

Muhammad B. Zaman

THE KIDNEYS

The role of cytology of the **urinary sediment** in the diagnosis of renal diseases is discussed in Chapters 22 and 23. The subject of this chapter is **transcutaneous fine-needle**

P.1458

aspiration (FNA) of the kidney. Dean (1939) first reported the treatment of a solitary cyst of kidney by aspiration. Söderström (1966) described a large experience with this method, and Von Schreeb et al (1967), Kristensen et al (1972), Thommesen and Nielsen (1975), Edgren et al (1975), and Holm et al (1975) each reported a series of cases.

It must be stressed at the outset that FNA **does not replace renal core biopsies in the diagnosis of diffuse medical diseases of the kidney; however, it does play a role in the assessment of renal transplant rejection** (see below).

INDICATIONS

FNA is used for the **pretreatment diagnosis of space-occupying lesions of the renal parenchyma.** Although renal cell carcinoma (RCC) is as common as pancreatic carcinoma, only 5% of all transcutaneous abdominal aspirations performed at the Westchester Medical Center are directed toward renal lesions, as compared to 12% for the pancreas. This is because a reliable diagnosis of renal neoplasms can be established in most patients by renal imaging studies consisting of **intravenous pyelography, ultrasonography (US), computed tomography (CT), and arteriography**, obviating the need for a preoperative biopsy. Each of these imaging techniques has a low, but significant, diagnostic error rate (Sherwood and Trott, 1975; Richter et al, 2000). We know of cases of nephrectomy performed for a benign neoplasm, cyst, or benign adrenal tumor mimicking renal masses.

FNA biopsy of renal abnormalities can provide a **definitive diagnosis** and considerably reduce surgical exploration of patients with **nonneoplastic lesions, such as cysts, and may clarify the nature of solid lesions that are not clearly defined by imaging procedures** (Zornoza et al, 1977a; Meier et al, 1979; Barbaric et al, 1981; Murphy et al, 1985; Nadel et al, 1986; Pilotti et al, 1988; Leiman, 1990; Cristallini et al, 1991).

The indications for FNA biopsy of **space-occupying lesions** of the kidney are as follows:

- **Cystic lesions (as a diagnostic and therapeutic procedure)**
- **Lesions with equivocal radiologic findings**
- **Confirmation of diagnosis in advanced malignant lesions prior to nonsurgical**

treatment

- **Confirmation of local recurrence at the site of a prior tumor or a direct extension from neighboring site (e.g., colon or adrenal)**
- **Confirmation of metastatic cancer**

Transcutaneous FNA biopsy has been used for the **follow-up of renal allograft recipients** (Häyry and von Willebrand, 1981a). The technique was described in detail by Häyry and von Willebrand (1981b, 1984), and was used successfully by Bishop et al (1989), Linsk and Franzén (1989), Egidi (1990), and Garcia-Castro et al (1993). As described in detail in Chapter 22, the aspiration specimen is used to identify subpopulations of T-lymphocytes by immunocytochemical or flow cytometric analysis.

Aspiration cytology has been used in Scandinavian countries to **grade renal carcinomas**, in order to select patients with high-grade (poorly differentiated) tumors for preoperative radiotherapy (Zajicek, 1979). This issue is discussed below.

TECHNIQUE OF ASPIRATION BIOPSY

The FNA technique is patterned after that used for renal core biopsies. Söderström (1966) approached this type of biopsy on **purely anatomic grounds**, without roentgenologic or US guidance. Others have used biplane **fluoroscopic guidance**, usually with intravenous pyelography (IVP). Developments in **US and CT** have significantly improved the guidance system in adults and children (Kristensen et al, 1974; Zeis et al, 1976; Juul et al, 1985; Nguyen, 1987; Thornburg and Weiss, 1987; Li Puma, 1988; Pilotti et al, 1988). These techniques do not depend on renal function, as does IVP, and they are helpful in separating solid from cystic lesions and cystic neoplasms from benign cysts (Pollack et al, 1982).

The principles of the aspiration procedure are discussed in Chapter 28. **The special requirements for renal FNA** are as follows: Regardless of the guidance modality used to target the renal lesion, the aspiration is usually undertaken with the **patient in either a prone or decubitus position**, which allows for the shortest possible skin-to-lesion distance. When a 22- or 23-gauge needle is used, it may be difficult to penetrate the tough renal fascia. Thus, Zajicek (1979) advocated the use of a larger-caliber needle with an obturator as a guide for the thinner needle. In our experience, this is rarely required.

Complications

In an early study, von Schreeb et al (1967) found **no differences in the survival rates** of patients who underwent an aspiration and those who did not. Söderström (1966) reported some instances of **hematuria**. A case of **seeding of renal carcinomas in the needle track** (with an 18-gauge needle) was described by Gibbons et al (1977). Additional reports of needle-track seeding with smaller-caliber aspiration needles have been described (Auvert et al, 1982; Wehle and Grabstald, 1986; Shenoy et al, 1991; Smith, 1991; Slywotzky and Maya, 1994).

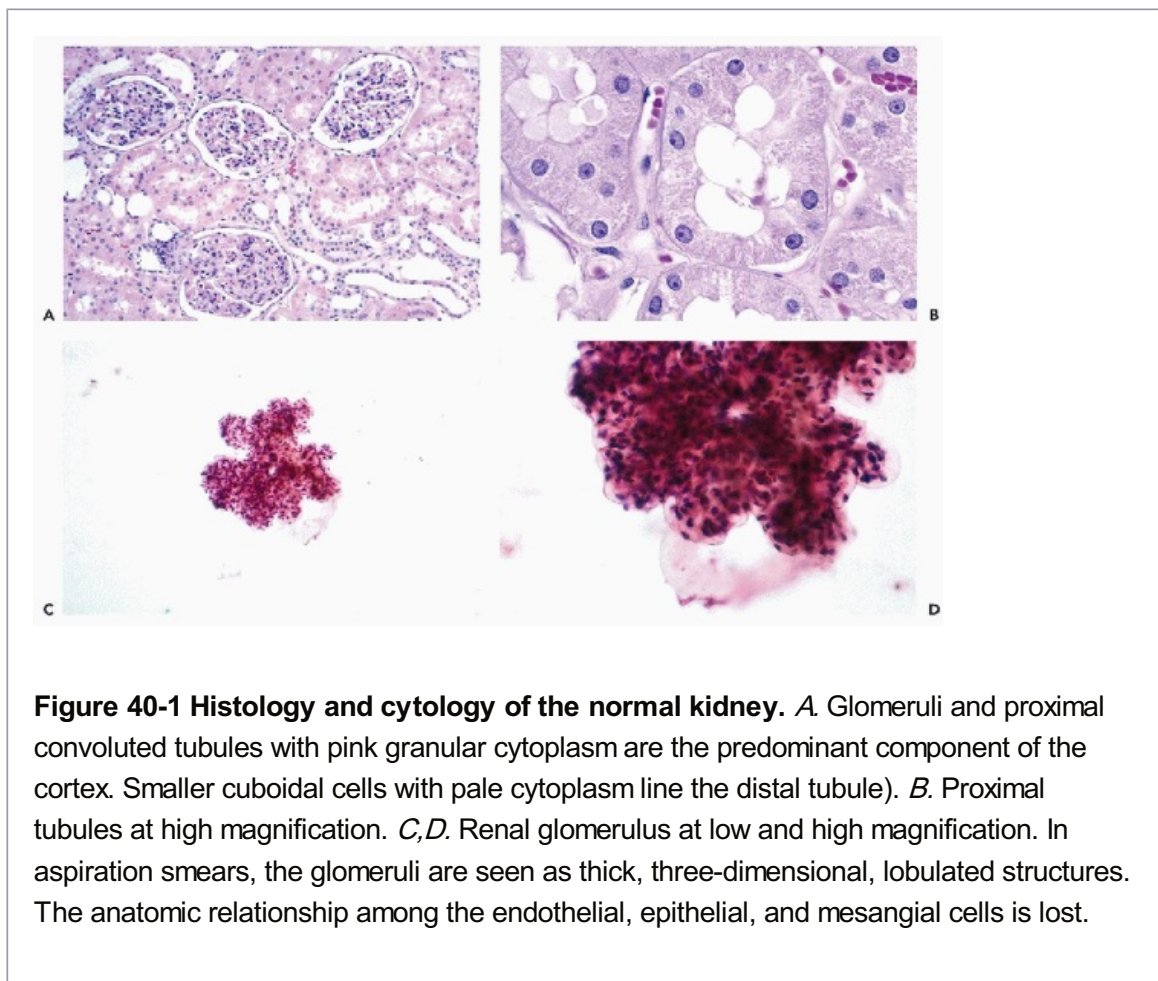

SYNOPSIS OF ANATOMY AND HISTOLOGY

The essential features of anatomy of the kidney are briefly summarized in Chapter 22. A few additional points of special interest regarding aspiration biopsy may be added here. The **right kidney is adjacent to the inferior surface of the liver, the right colic flexure, and the small intestine, and the left kidney is adjacent to the spleen, the body of the pancreas (and splenic vessels), the stomach, the left colic flexure, and the small intestine.**

Therefore, **extrinsic cells** from any of these organs, as well as **mesothelial cells** from peritoneal reflections and **perirenal fat**, are not uncommon in renal aspirates.

P.1459

Each kidney is composed of an external or cortical zone (**cortex**), an internal medullary zone (**medulla**), and the **renal pelvis**, which **opens into the ureter**. Renal parenchyma consists of one to two million **nephrons**, interstitial connective tissue, and a very rich and complex network of blood vessels arranged in an exquisite order to carry on the function of blood filtration and excretion of waste products in the urine. Each **functional unit of the kidney**, or **nephron**, consists of a **glomerulus** in continuity with a **renal tubule** (Fig. 40-1). Each tubule is divided into a **proximal convoluted segment (the progenitor of common RCC)** and a **distal convoluted segment (the progenitor of papillary carcinoma)**, the two of which are connected by a narrow segment called the loop of Henle. The tubules drain the filtered urine into **collecting ducts**, which are lined by two distinct types of cells. The majority of these cells are light-staining **collecting duct cells (the progenitors of a rare tumor, collecting duct carcinoma (CDC))**, and the minority are dark-staining **intercalated cells** with many mitochondria (**the progenitors of oncocytoma and chromophobe RCC (ChRCC)**). Collecting ducts coalesce to form the **terminal ducts of Bellini**, which carry the urine into the renal pelvis. For further comments on the formation of urine, see Chapter 22.

The **glomeruli** are located mainly in the renal cortex (Fig. 40-1A). They are complex, spherical structures composed of capillary tufts with specialized endothelial cells supported by mesangial connective tissue cells. Each glomerulus is surrounded by a connective tissue envelope, known as **Bowman's capsule**.

The tubules make up the largest component of the kidney parenchyma. The tubules are lined by **cuboidal epithelial cells** that may stain intensely pink or pale in hematoxylin and eosin (H&E) stain, and vary in size depending on their function and location in the tubular segment (Fig. 40-1B). Although several types of tubular cells may be distinguished by ultrastructural and other studies (Bander et al, 1985), they cannot be reliably subclassified in aspiration smears.

As described in detail in Chapter 22, the renal calyces and pelvis are lined by **urothelium**, which occasionally may be seen in aspiration smears of the lower pole of the kidney.

CYTOLOGY OF NORMAL KIDNEY

In material aspirated from renal cysts and sometimes from relatively small renal tumors, **benign renal tubular cells**

P.1460

are often observed. However, unless a large-bore needle is used, **intact glomeruli** are rarely encountered (Fig. 40-1C,D).

An **intact glomerulus** is large enough to occupy nearly the entire 40× microscopic field. It is a **sharply circumscribed, lobulated, round or oval, thick, multilayered structure composed of small cells**. Because the glomeruli are squashed on the slide, their internal structure cannot be seen. **Bowman's capsule** may be seen on rare occasions as a balloon-like transparent membrane.

The **normal tubular cells** are sometimes aspirated as intact tubules (Fig. 40-2A) or as epithelial cells, either dispersed or forming small clusters (Fig. 40-2B-D). The cells of proximal tubules, which have eosinophilic cytoplasm, are not easy to identify as such, and in fact may mimic cells derived from normal adrenal cortex and sometimes well-differentiated small malignant cells derived from papillary or low-grade conventional RCC (see below). The normal tubular cells are generally **cuboidal in shape** and **vary in size** from small cells derived from the loop of Henle to the much more common larger cells derived from the proximal and distal tubules. Most of the larger tubular cells display a relatively abundant **finely granular, transparent, pale or pink cytoplasm**, depending on the stain used, and **small, spherical nuclei with transparent chromatin pattern, containing tiny nucleoli**.

Figure 40-2 *A.* Whole renal tubules in aspiration smears. *B.* Proximal tubular cells. Note that the majority of the nuclei are separated from each other by pink granular cytoplasm. *C, D.* Tubular cells forming sheets in MGG-stained smears. Note the uniformity of the cells and their small nuclei.

BENIGN LESIONS

Renal Cysts

Cystic diseases of the kidney are a heterogeneous group of lesions that include **hereditary, congenital but nonhereditary, and acquired disorders**. Renal cysts may be **tiny or very large** (measuring 10 cm or more in diameter), **single, or multiple**. In the hereditary **polycystic kidney**, nearly all of the adult kidney can be replaced by cysts of various sizes (which, incidentally, **should not be aspirated unless there is a suspicion of a coexisting renal carcinoma**).

Acquired cysts are the most common renal lesions. They are usually **small and unilocular**, and are formed by shrinkage of the renal parenchyma secondary to vascular insufficiency in elderly patients. They are rarely a cause for alarm. **Dialysis-associated cystic disease** affects patients with chronic renal failure and prolonged dialysis. End-stage kidneys are often shrunk and multicystic, and have been reported to carry an up to 50-fold increased risk of **RCC** (Truong et al, 1995).

Cystic nephroma, or multilocular cyst of the kidney, is a rare benign neoplasm that occurs in children or young adults (usually female). The cysts are unilateral and encapsulated. The compartments of the cyst, or **locules**, are lined by a single layer of epithelium with or without atypia (Eble and Bonsib, 1998).

P.1461

Except for the adult form of polycystic kidney, most renal cystic lesions are **asymptomatic and incidental**. Sometimes, however, renal cysts may present a diagnostic dilemma and may be confused with renal carcinomas undergoing cystic degeneration (Pollack et al, 1982).

Cysts have been the most commonly aspirated renal lesions since the first report by Dean (1939) was published. If the preaspiration diagnosis of a cyst is secure, a **large 18-gauge needle** may be used to evacuate the cyst fluid. In less secure cases, it is preferable to use smaller-caliber needles.

Inspection of Cyst Fluid

The amount of fluid aspirated from renal cysts varies according to cyst size. In exceptional cases, 40-50 ml of fluid may be aspirated. In most instances, the fluid is clear, straw-colored, and occasionally cloudy or blood-tinged, or, rarely, chocolate brown, suggestive of a prior hemorrhage. Zajicek (1979) and Pilotti et al (1988) suggested that **clear, straw-colored fluid does not require cytologic study because** the fluid in cystic RCCs is usually cloudy and discolored (Rehm, 1961; Khordand, 1965; Holm, 1975; Anderson, 1977). Our policy is to study the cytologic make-up of all aspirated fluids.

Cytology

Clear cyst fluid from the diverse group of renal cysts described above may be **acellular** or may show a variable number of **mononucleated and, rarely, multinucleated macrophages**

(Fig. 40-3). Rare clusters of benign epithelial cells from cyst lining or **benign tubular cells** from the surrounding normal renal parenchyma may be encountered. **Reactive fibroblasts** from the capsule of the cyst may also be seen. Occasionally, the macrophages may show **significant nuclear abnormalities** that at a first glance may be thought to represent cancer cells. The correct diagnosis is best established by searching for some **evidence of phagocytosis** in the cytoplasm of these cells. **Liesegang rings**, approximately spherical concentric structures, have been reported in renal cyst fluid (Sneige et al, 1988; Katz and Ehya, 1990; Raso et al, 1998) (see Chap. 25).

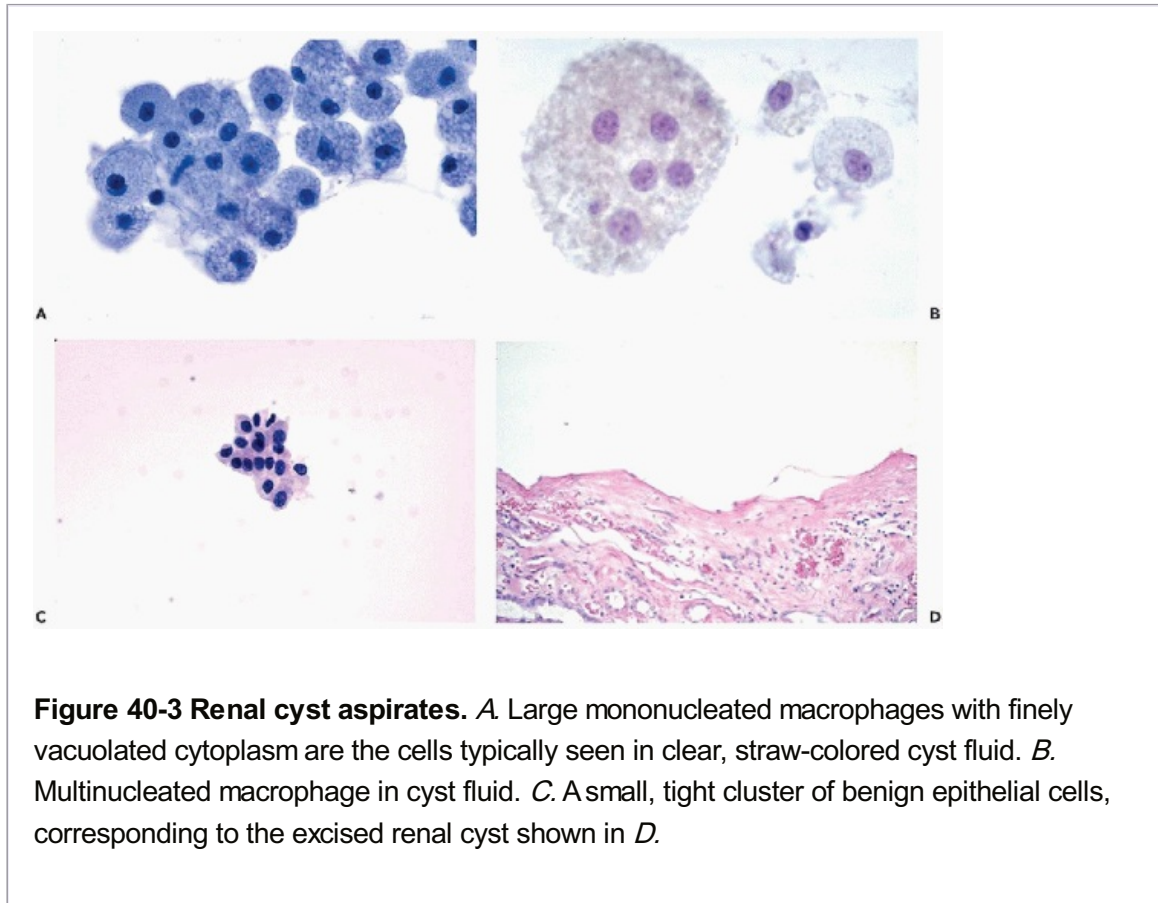

Figure 40-3 Renal cyst aspirates. *A.* Large mononucleated macrophages with finely vacuolated cytoplasm are the cells typically seen in clear, straw-colored cyst fluid. *B.* Multinucleated macrophage in cyst fluid. *C.* A small, tight cluster of benign epithelial cells, corresponding to the excised renal cyst shown in *D.*

Cloudy fluid is generally derived from **an inflamed cyst** and contains numerous polymorphonuclear leukocytes (see below). The cytology of **cystic RCC** is described under neoplasms of the kidney.

Ancillary Studies of Renal Cyst Fluids

In our experience, additional information may be obtained by determining the **fat, protein, and lactic dehydrogenase (LDH) content** of the renal cyst fluid. Clear fluid from acquired cysts is low in fat, protein, and LDH. Cloudy or turbid fluid is generally inflammatory and therefore high in protein and very high in LDH. A malignant cystic tumor

P.1462

yields bloody fluid with high fat and protein but low LDH levels.

Renal Abscess

Patients with renal abscess are febrile and usually experience severe costovertebral angle pain, tenderness, and often pyuria. **Pyelonephritis**, whether of hematogenous origin or caused by an ascending infection, may result in a renal abscess. Commonly, an abscess is the **result**

of obstruction of the ureter by calculi or tumor, leading to hydronephrosis and secondary infection in neglected patients. The abscess may be limited to the renal pelvis or may involve the entire kidney and perinephric region, in which case the collection of pus may be quite large and may **mimic a cystic or a solid tumor**.

The **aspirate yields purulent exudate** that should be submitted for microbiologic study. In endemic areas, **tuberculosis** must be considered as a cause of renal abscess.

NONCYSTIC BENIGN RENAL DISORDERS

Renal Infarcts

Because renal infarcts **may mimic a renal tumor in imaging studies**, they are occasionally aspirated. Silverman et al (1991) reported two such cases. In one case, necrotic glomeruli and tubules were observed; in the second, **atypical tubular renal cells** (presumably the consequence of tubular regeneration) were **mistaken for an RCC**. Thus, renal infarcts must be considered in the differential diagnosis of renal tumors.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is an unusual, relatively rare form of chronic pyelonephritis characterized by the accumulation of **foamy macrophages intermixed with plasma cells, lymphocytes, polymorphonuclear leukocytes, and occasional giant cells**. The clinical findings include flank pain, renal mass, hematuria, and recurrent urinary tract infections, usually caused by the ***Proteus* species**. **Staghorn calculi** may be present. **The radiologic findings** of a **hypovascular nonfunctioning renal mass** may be difficult to interpret. **Grossly**, there are discrete or confluent large, **yellowish-orange nodules within the enlarged kidney** that may be confused with RCC. On microscopic examination of tissue sections, the clusters of histiocytes with abundant, clear, foamy cytoplasm may superficially **resemble clear cell renal cortical carcinoma**. Akhtar and Qunib (1992) reported a case of bilateral xanthomatous pyelonephritis associated with **amyloidosis and a small renal carcinoma** in one of the native kidneys of a patient who had undergone a renal transplant.

Cytology

The FNA biopsy shows a polymorphous picture of **macrophages and giant cells** with **foamy vacuolated cytoplasm** in a background of necrosis and inflammatory cells. The findings may superficially suggest clear cell carcinoma, but usually are sufficiently characteristic to establish a cytologic diagnosis (Lizza et al, 1984; Sugie, 1991).

Malakoplakia

There are several cases of renal malakoplakia on record (for a summary see Esparza et al, 1989). Hurwitz et al (1992) reported a case of **bilateral** malakoplakia. Although to our knowledge there are no reported cases of renal malakoplakia diagnosed on FNA, this possibility should be kept in mind for future reference. The histology and cytology of this disorder are extensively discussed in Chapter 22.

Benign Renal Neoplasms

Angiomyolipoma

Renal angiomyolipoma occurs in **two distinct clinical settings**. It occurs **either as a large,**

single tumor in otherwise normal patients, or as **multiple bilateral smaller tumors in patients with tuberous sclerosis**, a disorder characterized by mental retardation, epilepsy, and multiple sebaceous adenomas of the skin (Bennington and Beckwith, 1975; Brodsky and Granick, 1989; Silva and Childers, 1989). The tumor may also occur in the **retroperitoneum** (Wadih et al, 1995) and the **liver** (Nguyen and Catzavelos, 1990). With the widespread use of modern imaging modalities, more and more asymptomatic angiomyolipomas of the kidney have been diagnosed. The tumor has very characteristic **features on CT** (Fig. 40-4A). The presence of **fat**, accounting for **clear areas**, differentiates this tumor from renal carcinoma (Bosniak et al, 1988). On **angiography**, the tumor is vascular and may **mimic RCC**. However, benign and usually asymptomatic, large angiomyolipomas are often resected for fear of severe or, rarely, fatal hemorrhage.

Histology

Renal angiomyolipoma is a benign neoplasm that is composed of a **mixture of smooth muscle, fat, and tortuous, thick-walled blood vessels** (Fig. 40-4B,D). Some of these tumors are **very cellular** and may show **mitotic activity in smooth muscle cells**. Some of the spindly cells may show marked nuclear abnormalities in the form of **large and hyperchromatic nuclei in bizarre spindly cells** with abundant eosinophilic cytoplasm. In some tumors, **giant cells with huge nuclei and prominent nucleoli** may be observed (Eble et al, 1997). Such tumors may be confused with malignant mesenchymal tumors, leiomyosarcomas, or renal sarcomatoid carcinomas. The presence of **needle- or rod-shaped crystalloids** in the cytoplasm of the tumor cells was reported by Mukai et al (1992). In most instances, the characteristic histologic pattern is recognizable, particularly because of the presence of fat (Silva and Childers, 1989). The **immunohistochemical profile** of angiomyolipoma is rather distinctive. The **cytokeratin stain is negative**, whereas **actin** stain is strongly positive, in keeping with the smooth-muscle derivation of the tumor cells. **Vimentin stain** is variable, but **HMB-45 (melanoma antigen) stain is positive** in perivascular spindly epithelioid cells of the tumor. This panel of stains may be helpful in identifying this tumor in debatable cases.

P.1463

Figure 40-4 Angiomyolipoma. Angiomyolipoma of the left kidney in a 34-year-old woman with no evidence of tuberous sclerosis. *A.* Computed tomography (CT) revealed the tumor in the lower pole of the right kidney. The patient was in a prone position. The CT features were characteristic of angiomyolipoma, notably because of the presence of clear areas representing fat within the tumor. *B, D.* Tissue sections. *B.* Numerous thick-walled vessels, smooth muscle cells, and fat are present. *D.* Bundles of smooth muscle cells. Note the presence of pleomorphic, atypical nuclei. *C, E, F.* Aspirate. *C.* Irregular tissue fragments containing smooth muscle cells, fat, and vessels. *E.* Tissue fragment. Note the irregular arrangement of the nuclei and their variable sizes. *F.* Group of cells with abundant cytoplasm. Note the significant differences in nuclear sizes. Most of the nuclei are hyperchromatic, but their contour is smooth. These cytologic features may lead to an erroneous diagnosis of a carcinoma or a sarcoma. (From Koss et al. *Aspiration Biopsy. Cytologic Interpretation and Histologic Bases*, 2nd ed. New York: Igaku-Shoin, 1992.)

Cytology

The **classical cytologic presentation** of an angiomyolipoma shows small tissue fragments composed of **fat and bundles of spindly cells** (Koss et al, 1992). Fragments of **thick-walled blood vessels** may be observed (Glenthoj and Partoft, 1984; Nguyen, 1984). Gupta et al (1998b) searched for the **crystalloids** described by Mukai et al (1992), but could not find them with either light or electron microscopy. Even at low power, some **variability in nuclear sizes within the spindly cells** may be observed (Fig. 40-4C). At higher power, the nuclear variability and hyperchromasia are evident (Fig. 40-4E,F). In some cases, **mitotic figures and very large, hyperchromatic nuclei** may be observed, which may lead to an **erroneous**

interpretation of the smear as an RCC (Nguyen, 1984; Granter and Renshaw, 1999).

Leiomyosarcomas and other spindle cell tumors must be considered in the differential diagnosis. In most cases, however, the **presence of fat should act as a deterrent to wrong interpretation** of the smears (Koss et al, 1992). If adequate material is available, immunostaining (discussed above) may also be helpful in establishing the correct identity of the tumor.

P.1464

Renal Adenoma

Papillary (Chromophil) Adenoma

Papillary (chromophil) adenoma is a controversial lesion, primarily defined by its size of 1 cm or less in diameter. Nearly all lesions are asymptomatic and found incidentally. It is not known whether the lesion is related to papillary renal carcinomas, even though there is some histologic similarity, and such lesions are commonly found in kidneys with clinically evident papillary RCC (Reuter and Gaudin, 1999). The tumors are **well demarcated but nonencapsulated**, pale gray to yellow nodules in a cortical or subcapsular location. Histologically, they are composed of **densely packed tubules lined by small, regular cuboidal cells with round, uniform, bland nuclei**. **Tubulopapillary**, purely **papillary** patterns and **microcyst** formation have been noted (Grignon and Eble, 1998).

The **FNA experience** with these very small lesions is very modest. Kini (1999) reported tissue fragments composed of uniform small cells with high nucleocytoplasmic (N/C) ratios.

Congenital Mesoblastic Nephroma of Infancy

Congenital mesoblastic nephroma of infancy is an uncommon **benign** tumor that was first described by Bolande et al (1967). The tumors may be bulky and palpable in newborns and infants, and are composed of **proliferating fibroblasts and smooth muscle cells** with preservation of the nephrons. Drut (1992) and Kaw (1994) described the cytologic findings in FNA in such cases. **Benign spindle cells arranged in bundles** were the dominant feature. Of note was the **presence of epithelial cells derived from renal glomeruli and tubules** that could have been mistaken for an epithelial component of a malignant stromal tumor, such as Wilms' tumor (see below).

Metanephric (Embryonal) Adenoma

Metanephric (embryonal) adenomas are rare benign renal cortical neoplasms that are included in the new classification of renal neoplasms (Table 40-1). These tumors occur in all age groups, most often in women, and produce **nonspecific symptoms of a renal mass**. **Hematuria** may occur. **Polycythemia** has been reported in as many as 12% of patients (Hennigar and Beckwith, 1992; Davis et al, 1995).

Figure 40-5 Metanephric adenoma. *A.* Histology. Closely packed tubular structures with papillary infolding (glomeruloid bodies). The tumor cells are monotonous and small with scanty cytoplasm. *B.* Touch-preparation of a nephrogenic adenofibroma (see text).

TABLE 40-1 CLASSIFICATION OF RENAL CELL NEOPLASMS

Benign neoplasms (partial listing)

Oncocytoma^{*}

Tumor of undetermined malignant potential

Multilocular cystic RCC

Adapted from the Heidelberg classification of renal cell tumors (Kovacs et al, 1997).

* In this text, oncocytoma is discussed with malignant neoplasms.

Histology

Metanephric adenoma is characterized by **tightly packed tubules with papillary infoldings, mimicking to some extent the configuration of glomeruli (glomeruloid bodies)** (Fig. 40-5A). Similarities with Wilms' tumor have been stressed (Davis et al, 1995; Jones et al, 1995). **A cytogenetic analysis showing trisomies of chromosomes 7 and 17, and loss of sex chromosome Y suggested that these tumors are**

P.1465

related to papillary RCC, which shows similar findings (Brown et al, 1997). We recently encountered a case of papillary carcinoma that arose in a metanephric adenoma, confirming the relationship between the two lesions.

Cytology

Renshaw et al (1997) described the cytologic pattern of a metanephric adenoma studied by FNA in a 48-year-old woman with a tumor 4 cm in diameter. The **monotonous small tumor cells with scanty cytoplasm, spherical nuclei, and occasional small nucleoli** were arranged in **short, tight papillary clusters and loose sheets**. Stains for **keratin, epithelial membrane, and carcinoembryonic antigens were negative**. Zafar et al (1997) described two such cases with essentially similar findings. In one of these cases, **a preoperative diagnosis of Wilms' tumor** was made. We have had experience with a **touch preparation** of one **nephrogenic adenofibroma** (see following topic), which showed only **small epithelial cells, closely resembling blastema cells of Wilms' tumor** (Fig. 40-5B), in keeping with the observations of Renshaw et al (1997) and Zafar et al (1997). Thus, the similarities between the cytology of benign metanephric adenoma and that of Wilms' tumor are striking. **The monotonous population of small cells in metanephric adenoma in comparison with the triphasic morphology of Wilms' tumor, and to some extent the older age of patients with metanephric adenomas, may serve to differentiate these two types of tumor.** For a description of Wilms' tumor, see below.

Nephrogenic Adenofibroma and Other Uncommon Benign Lesions

Nephrogenic adenofibroma is a biphasic tumor composed of an **epithelial component**, similar to that of metanephric adenoma (Fig. 40-5A), which is separated by **bland fibro-blast-like cells** (Hennigar and Beckwith, 1992; Arroyo et al, 2001). Other benign entities that may present as space-occupying lesions of the kidney include **benign mesenchymal tumors (e.g., leiomyomas, fibromas, and angiomas)**. We have not seen any aspirated material from these lesions, and to our knowledge, no case descriptions have been published.

MALIGNANT TUMORS OF RENAL PARENCHYMA

In **adults**, most malignant renal tumors arise **from renal tubules** and are therefore designated as **RCC**. The old terms **hypernephroma** and **adenocarcinoma of the kidney** are no longer

considered appropriate. A small number of carcinomas arise from the **urothelium of the renal pelvis** and are identical to carcinomas of the bladder or ureter (see below and Chap. 23). **In children, Wilms' tumor** is the most common malignant renal tumor.

Nonepithelial malignant tumors (e.g., sarcomas) are exceedingly uncommon, and most arise in the renal capsule or hilum (Farrow et al, 1968).

Renal Cell Carcinoma (RCC)

Epidemiology and Genetics

RCC represents about 2% to 3% of all visceral cancers, and accounts for 85% of all renal cancers in adults, being more common in males than females. There are an estimated 31,800 new cases and 11,600 deaths per year from this disease in the United States (Jemal et al, 2002). The peak incidence is in the sixth and seventh decades of life.

A **hereditary form of RCC** has been described in families with an abnormality of the short arm of chromosome 3 (Cohen et al, 1979), accounting for a very small proportion of cases of this disease. Rare cases of RCC occur in people with **Von Hippel-Lindau disease** (i.e., the formation of abnormal vessels in the cerebellum and retinas), but most RCCs are sporadic and of unknown etiology. The customary villains—smoking and environmental factors—may play a role in the genesis of these tumors (McLaughlin et al, 1984; Yu et al, 1986). Dey et al (1996) described several cases of RCC in children.
